Because delinquency is defined according to acts prohibited by law, including theft, violence, vandalism, and drug use, many delinquent acts are symptoms of conduct disorder. Conduct disorder according to the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), is defined as a repetitive and persistent pattern of behavior in which the basic rights of others or major social norms or rules are violated, as manifested by at least three of fifteen criteria within the past 12 months, with at least one criterion present in the last 6 months. The criteria are divided into four categories: aggression to people and animals, destruction of property, deceitfulness or theft, and serious violations of rules. Childhood-onset type applies to individuals with onset of at least one symptom characteristic of conduct disorder prior to age 10; adolescent-onset type to those without symptoms characteristic of conduct disorder prior to age 10; and unspecified type in which the criteria for conduct disorder are met, but it is unclear as to whether the onset of the first symptom was prior to or after age 10 (American Psychiatric Association 2013). Callous–unemotional traits have been increasingly emphasized in theories regarding the etiology of conduct disorder (Frick et al. 2014), and in *DSM-5*, the specifier "with Limited Prosocial Emotions" (LPE) is applied to a

minority of youth who display at least two of the following characteristics over at least 12 months and in multiple relationships and settings: lack of remorse or guilt; callousness/lack of empathy; lack of concern regarding poor performance at work, school, or other important activities; and shallow or deficient affect. This specifier is expected to guide further research and treatment and provide more information about the impairment and prognosis of children and adolescents with conduct disorder. It appears that the LPE specifier identifies a group of more severely antisocial youth for both genders, with younger age of criminal behavior and legal contact (Pechorro et al. 2015).

Symptoms of conduct disorder usually emerge in middle childhood to middle adolescence, and the delinquency peaks in middle to late adolescence. The majority of youth who meet criteria for conduct disorder will not meet criteria for antisocial personality disorder in adulthood and will desist in their criminal activity; however, the early onset type of conduct disorder has a worse prognosis and increased risk for adult criminal behavior.

The Pittsburgh Youth Study, a longitudinal study of 1517 inner-city boys, purposefully contained an oversampling of boys with disruptive behaviors and contributed significantly to our understanding of the development and evolution of delinquency in boys (Loeber and Farrington 2012) The Pittsburgh Youth Study identified three distinct developmental pathways to delinquency in boys: (1) Authority Conflict pathway characterized by stubbornness prior to age 12, then moving on to defiance; (2) Covert pathway characterized by minor acts such as lying and stealing, and progressing to more serious delinquent acts; and (3) Overt pathway characterized by minor aggression progressing to more serious fighting and violence. The researchers noted delinquency typically follows an orderly progression, with "problem behaviors" beginning long before major behavior problems and legal involvement. Early risk factors such as irritability and impulsivity were obvious between ages 3 and 6 years of age (Moffitt et al. 1996).

Among the cohorts in the Pittsburgh Youth Study, 30%–51% of boys by age 15 at various levels of risk had committed serious crimes. In their delinquency model, as the child aged, more risk factors accumulated and exerted an influence. Each risk factor added weight to previous risk factors, and the more risk factors, the greater the likelihood of delinquency. The more risk factors present, the more difficult it is to return to a normal developmental path without intervention. However, most antisocial children do not go on to become antisocial adults. Likewise, it is highly unusual for antisocial behavior to arise *de novo* during adulthood without a childhood or adolescent history of antisocial behavior.

Risk factors are variables that when present predict an increased probability of conduct disorder or delinquency. Risk factors for delinquency can be divided into individual risk factors, family risk factors, and social risk factors (Murray and Farrington 2010).

Individual risk factors

Numerous individual factors have been described as increasing one's risk for the development of conduct disorder and delinquency, including irritability and depression (Burke et al. 2005), low self-esteem (Kokkinos and Panayioutou 2004), trauma-related psychopathology (Steiner et al. 2011), and temperament (Caspi 2000; Caspi and Silva 1995). However, the most extensive research has consistently identified impulsivity, low IQ, and poor school achievement as the major individual risk factors (Murray and Farrington 2010).

The Pittsburgh Youth Study found low IQ was related to offending in boys independent of socioeconomic status, ethnicity, neighborhood, and impulsivity. Personality factors include having a low threshold for experiencing negative emotions such as anger, fear, and anxiety, as well as thrill-seeking and impulsivity. Additional risk factors include a lack of guilt, being older than one's classmates, and depression (Loeber et al. 1998).

Family risk factors

Poor parental supervision is one of the strongest risk factors for delinquency and conduct disorder (Loeber et al. 2009). Harsh and/or inconsistent parental discipline and child abuse, parental conflict, antisocial parents, and parental imprisonment are strong predictors of child antisocial behavior (Murray and Farrington 2008, 2010).

Social risk factors

Low socioeconomic status (SES) has been associated with delinquency, although what mediates the link is unclear. Poor child-rearing practices and family factors such as corporal punishment and maternal care/unresponsiveness have been implicated, but delinquent peers may be a mediating factor (Fergusson et al. 2004). It is well known that juvenile offending, more so than adult offending, occurs in groups. Delinquent acts tend to be committed in small groups (two to three persons) rather than alone or in large groups (Zimring 1981). There appears to be a reciprocal relationship between delinquency and delinquent peer bonding; that is, association with delinquent peers causes delinquency, and delinquency causes association with delinquent peers (Thornberry et al. 1994). In the Pittsburgh Youth study, among social risk factors, receiving public assistance was associated with the highest risk of delinquency. Having a broken family was the strongest demographic variable related to delinquency, and living in a high-crime neighborhood more than doubled the risk (Loeber et al. 1998). Poor attachment to parents is yet another identified risk factor in delinquency (Hoeve et al. 2012).

Childhood abuse is associated with changes in gene expression (Suderman et al. 2014), brain structure, and neural networks, and may influence neurotransmitter function and levels in a way that persists into adulthood (Teicher et al. 2014). However, not all children who are abused

exhibit antisocial behavior. The interaction between genes and environment has been proposed as a mediating factor to explain the variability in the outcome of abused children. The monoamine oxidase A (*MAOA*) gene, which encodes the enzyme MAOA, plays a major role in the metabolism of the neurotransmitters dopamine, serotonin, and norepinephrine. A functional polymorphism in the *MAOA* gene in combination with self-reported maltreatment has been shown in some studies to impact delinquency (Caspi et al. 2002). Boys with a short variant of the polymorphism had a higher risk of delinquency when exposed to maltreatment; abused girls with at least one long variant of the polymorphism had a higher risk of delinquency (Aslund et al. 2011).

GENDER ISSUES AND THE DEVELOPMENT OF DELINQUENCY

Female juvenile delinquency has garnered increased research attention; however, overall there has been a paucity of research examining the causes and correlates of female delinquency relative to male delinquency. While overall, girls' delinquent acts are typically less chronic and severe than boys (Snyder and Sickmund 2006), it is a serious and growing problem. In 2011, girls accounted for one-third of juvenile arrests.

To date, there is no comprehensive theory of the development of delinquent behavior that is specific to girls; however, a number of large-scale studies have helped inform a better understanding of the development and maintenance of antisocial behavior in both males and females. The Pittsburgh Girls Study, a longitudinal community-based study of 2451 girls recruited when they were between the ages of 5 and 8 years, found that conduct disorder tended to have an insidious onset in girls, beginning with subsyndromal symptoms (Keenan et al. 2010).

In the landmark Dunedin Longitudinal Study, over 1000 boys and girls were followed from the ages of 3 to 21 using approaches and methods from developmental psychology, psychiatry, and criminology. The original taxonomy indicated two main types of antisocial behavior in youth (Moffitt 1993). The first type, life-course-persistent (LCP) antisocial behavior, is characterized by neurodevelopmental dysfunction (hyperactivity, central nervous system [CNS] dysfunction, learning disability [especially reading], and difficult temperament) along with social and familial deficits. LCP antisocial behavior has a significant male predominance, early onset in childhood, low prevalence (about 5%), and persistence into adulthood. The second type, adolescence-limited antisocial behavior, can be viewed as a social phenomenon. This type originates in the context of social relationships, has its onset during puberty, has a high prevalence, and has negligible sex differences, especially when drugs and alcohol are involved, and girls who are involved with antisocial males in intimate relationships (Moffitt and Caspi 2001; Moffitt et al. 2002). Risk factors include social and familial deficits such as poor supervision, broken homes, antisocial role models, and the perception of antisocial behavior as reinforcing. Girls are less likely to develop the more persistent developmental type of antisocial behavior because they more frequently lack the crucial risk factors for it (impulsivity, neurocognitive deficits, temperamental undercontrol). However, girls are as likely to develop the socially influenced form of antisocial behavior as boys with whom they share the same risk factors.

PSYCHOPATHOLOGY AND JUVENILE DELINQUENCY

Mental illness is prevalent among youth in the juvenile justice system. One study showed that among 1829 detained youth, nearly two-thirds of boys and nearly three-quarters of girls met diagnostic criteria for one or more psychiatric disorders. When conduct disorder was excluded, nearly 60% of boys and more than two-thirds of girls met criteria with impairment for one or more psychiatric disorders. Substance abuse disorders were found in half the boys and almost half of the girls (Teplin et al. 2002). Mood disorders are highly prevalent in this population. A study of 1024 incarcerated adolescents found that 60% had one or more psychiatric disorders; 25% had moderate depression, and 22% had severe depression as measured by the Beck Depression Inventory. From the Patient Health Questionnaire, 10% had major depressive disorder, 41% had drug abuse, 27% abused alcohol, and 29% had another major mental disorder. Comorbidity was especially common between depression and anxiety and drug and alcohol abuse. Sixty percent had one or more psychiatric disorders. Of those adolescents who were depressed, 20% had been previously diagnosed and treated compared to only 10% of youth with other disorders (Domalanta et al. 2003).

Abuse and trauma are strongly associated with risk-taking behaviors. Abuse is associated with alterations in the biological stress response system, which in turn can disrupt emotional and cognitive processes (Teicher et al. 2014), increasing the likelihood of risky behaviors in vulnerable youth. Girls in the juvenile justice system are more likely than non-juvenile-justice-involved girls to have experienced trauma, and were more likely to have experienced sexual abuse than boys (Wasserman and McReynolds 2011). In a large sample of detained inner-city youth, over 90% of the study participants had experienced at least one traumatic event, with 11% of the sample meeting full criteria for post-traumatic stress disorder (PTSD) within the past year (Abram et al. 2004). Among detained youth with PTSD, 93% met criteria for at least one other psychiatric disorder (Abram et al. 2007). Delinquent youth are more likely than nondelinquent youth to have experienced trauma and to report PTSD, major depression, and substance abuse. Even when accounting for the effects of demographics and trauma exposure, delinquency increases the likelihood of further traumatization and substance abuse in both genders, and increases the likelihood of major depression in girls (Adams et al. 2013). Other studies have found a higher prevalence of PTSD (30%), particularly among girls

Table 41.1 Overall prevalence of psychiatric disorders among incarcerated youth

Mental illness	Male %	Female %
Major depressive disorder	10.6	29.2
Psychotic disorders	3.3	2.7
Attention deficit hyperactivity disorder	11.7	18.5
Conduct disorder	52.8	52.8

(Cauffman et al. 1998; Ariga et al. 2008). The results of a meta-analysis consisting of 25 studies on the prevalence of mental disorders in incarcerated juveniles are summarized in Table 41.1 (Fazel et al. 2008).

During the past decade, most states have enacted policies requiring at least mental health screening in their juvenile justice population. The Massachusetts Youth Screening Instrument-Version 2 (MAYSI-2) is a brief mental health screening tool that can be completed by nonclinicians at entry to a juvenile justice facility (Grisso et al. 2001, 541–548) in order to identify youth who may need immediate attention for suicidal risk and emergent mental health and substance abuse problems. Over 2000 juvenile detention or correction facilities in 44 states use a version of the MAYSI-2 for mental health screening (Grisso et al. 2012).

TREATMENTS FOR JUVENILE DELINQUENCY

There are a number of empirically validated interventions for delinquency, which are unfortunately unavailable to the majority of youth who could profit from them, in large part because of their cost and the inertia that is part and parcel of an entrenched system. Many delinquent youth receive no evidence-based treatment; many receive interventions that might be helpful or even necessary but require combination with appropriate wrap-around services. Unfortunately, psychopharmacology and some form of individual therapy or home-based services provided by persons with little specialized training remains the mainstay of treatment for most delinquents receiving care. Of course, psychiatric disorders must be treated aggressively and appropriately, but pharmacologic treatment is only one intervention. Evaluation and treatment of substance abuse are another important focus for many delinquent youth.

Evidence-based treatments typically involve a treatment "package" that must be delivered consistently over a sufficient period of time to be effective. The treatment modalities should be individualized and may involve individual, group, and family therapy; psychiatric evaluation and pharmacologic treatment; education- and school-based interventions; and effective and aggressive case management.

Psychodynamic psychotherapy is generally suitable for only a minority of delinquent youth with internalizing disorders, such as depression and anxiety, who are reflective, trusting, and willing to engage in a therapeutic relationship. However, given the nature and causes of delinquency, even youth who may profit from psychodynamic psychotherapy should receive other needed services that address the myriad of stressors and vulnerabilities in the juvenile's life. The last two decades have seen the rise of empirically validated interventions specifically geared toward delinquent youth, several of which are described below.

Multisystemic therapy (MST) has been one of the most extensively studied interventions in delinquent youth (Henggeler et al. 1996). MST has been studied and shown to have a positive effect over traditional supportive therapies in subsets of delinquent youth including those with substance abuse and sex offenses (Zajac et al. 2015). The MST model mandates attention to altering a variety of maladaptive and risk-sustaining factors in the youth's life and is essentially a family-based intervention. Adherence to the treatment model, which emphasizes that case managers take responsibility for the adherence of the youth and family to treatment, is quite different from the more traditional mental health model, which often tends to blame the patient and family for lack of efficacy. However, a multilayer meta-analysis of 22 international studies consisting of 4066 juveniles showed only a small positive effect on delinquency (van der Stouwe et al. 2014). The meta-analysis indicated larger effects were found in the U.S. studies, and that MST was most effective with nonethnic minority, sex-offending, younger juveniles (under age 15). The authors suggested the efficacy of MST for older juveniles might be improved by focusing on peer relationships and risks and protective factors in the educational domain/school setting.

Functional family therapy (FFT) and multidimensional treatment foster care (MTFC) are family-based treatments that include a variety of additional components individualized to the particular youth (individual, psychiatric, peer, school, and community). Functional family therapy focuses on modifying patterns of family interaction by modeling, prompting, and encouragement, in an effort to develop clear and direct communication and minimize conflict (Alexander and Parsons 1973). A long-term follow-up study of juvenile offenders found FFT to be superior to probation services (control), with FFT participants reporting a lower rate of rearrests compared to controls (Gordon et al. 1995). Multidimensional treatment foster care focuses on individual treatment including problem-solving skills and parent management training for families of adolescents in foster care (Chamberlain and Reid 1998). This therapy has been found to be more effective than services-as-usual group home care for adolescent males in the juvenile justice system, with the self-reported rates of violent offending four to five times higher in the group home population (Eddy et al. 2004).

The Stop Now and Plan (SNAP) program has shown promise as an intervention for antisocial behavior among

boys between the ages of 6 and 11. A randomized controlled treatment effectiveness study showed improvements in aggression and other externalizing behaviors, as well as attention deficit hyperactivity disorder (ADHD) symptoms versus standard behavioral health services (Burke and Loeber 2014).

DELINQUENTS GROWN UP

What happens to juvenile delinquents in adulthood? The good news is the majority of juvenile offenders do not go on to develop antisocial personality disorder or become adult criminals. The bad news is juvenile delinquency exacts a significant price from the future of the individual child, and ultimately society. In their cohort of 1653 formerly detained youth, Abrams and colleagues found that 3 years after detention most youth struggled in one or more life domains, and more than one in five had marked impairment in functioning (Abram et al. 2009).

The boys and girls of the Dunedin study were assessed at age 32 years (Odgers et al. 2008). Four antisocial pathways were identified: (1) life-course persistent (LCP), which made up 10.5% of the males and 7.5% of the females; (2) adolescent-onset, which accounted for 19.6% of the males and 17.4% of the females; (3) childhood-limited (CL), which was 24.3% of the males and 20% of the females; and the largest group (4) antisocial low (AL), exhibiting low levels of conduct problems, which was 45.6% of the males and 55.1% of the females. The LCP males and females had the worst mental health, physical health, and economic outcomes, and early childhood antisocial behavior persisted into adulthood. The LCP pathway for both males and females was predicted by individual risk factors such a low IQ, reading disability, and hyperactivity, in combination with social and familial risk factors. The antisocial-low group had conduct problems that emerged in adolescence and persisted into adulthood (hence, the term "adolescence-limited" was not appropriate), but there was not an elevated risk of violence, and the mental health problems in these males and females were primarily restricted to substance abuse. The CL group had conduct problems that emerged during early childhood but desisted. The CL females at age 32 were not experiencing problems relative to their peers, but the males were behind in median household income and educational attainment.

SUMMARY KEY POINTS

- Juvenile crime peaked in the early 1990s and has steadily declined since that time; however, laws enacted in response to that increase remain in effect, resulting in harsher penalties for youth, including transfer to the adult system.
- The majority of youth who meet criteria for conduct disorder do not go on to become antisocial adults.
- Individual, family, and social risk factors for delinquency and persistent criminal behavior, including maltreatment, have an additive effect, and the more risk factors, the more likely a child will become delinquent.
- Mental illness, especially mood and anxiety disorders and substance abuse, is prevalent among youth involved in the juvenile justice system.
- There are a variety of empirically validated treatment interventions for juvenile delinquents.

Posttraumatic stress disorder in children and adolescents: Clinical and legal issues

FRANK K. TEDESCHI AND STEPHEN B. BILLICK

INTRODUCTION

References to what is now called posttraumatic stress disorder (PTSD) can be found in a wide range of historical texts spanning centuries, including the Bible, Homer, Herodotus, and Shakespeare. The symptoms that are recognized today as belonging to the well-defined psychiatric disorder that can result from exposure to trauma have also gone by other names, including "railway spine," "traumatic hysteria," "shell shock," and "combat fatigue" (Smith 2011). However, for much of its history PTSD has been referred to as a disorder of adults, with the initial *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition (*DSM-III*) criteria for PTSD being based primarily on studies of war veterans and adult rape victims (American Psychiatric Association 1980; March 1993). Despite this, there has long been recognition within the fields of psychology and psychiatry that children and adolescents develop posttraumatic symptoms as well, and may manifest these symptoms differently than adults depending on their age and developmental stage. Serious examination of the effects of trauma in children was first mentioned in literature during World War II (Dunsdon 1941; Brander 1943; Freud and Burlingham 1943), but it was not until 1987 that the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition, revised (*DSM-III-R*) incorporated developmental specifiers for children and adolescents in the PTSD criteria (American Psychiatric Association 1987). Though the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*) further expanded the developmental specifiers for PTSD (American Psychiatric Association 1994), the PTSD criteria in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*) is the most developmentally informed to date, with a greater emphasis on the behavioral sequelae of trauma for children age 7 and above, and the creation of the first developmental subtype of a *DSM* disorder: posttraumatic stress disorder for Children 6 Years and Younger (American Psychiatric Association 2013a).

The uniqueness of PTSD in the forensic context is the ability to directly link the development of psychopathology to an exposure of a traumatic event. As a consequence, PTSD is becoming one of the most commonly litigated mental health disorders (Bottalico and Bruni 2012). The diagnosis can be used in court to illustrate tangible proof of loss of functioning, as evidence that an alleged crime occurred, as well as a means of determining civil compensation. In this context, as research on PTSD has progressed, courts have increasingly turned not only to the psychiatric interview as a means of establishing the diagnosis, but also neuroimaging and neurological manifestations of the disorder (Lubit et al. 2002). This is particularly important as courts have historically tended to award damages more commonly for injuries that are considered "physical," rather than purely "psychological" (Lubit et al. 2002). With children and adolescents the evaluation of PTSD has an additional layer of complexity, due to their different cognitive, emotional, language, and memory capacities. The expert must be well versed not only in specific *DSM-5* criteria, but also in models of pediatric development, neuroimaging research in juveniles, and forensic interviewing techniques for children and adolescents. The expert must also be prepared to perform evaluations and testify in an ever-expanding range of civil and criminal proceedings, including personal injury, medical malpractice, violent crime, physical and sexual abuse, neglect, custody evaluations, and the termination of parental rights.

POSTTRAUMATIC STRESS DISORDER IN THE *DSM-5*

Though the *DSM-IV* (American Psychiatric Association 1994) expanded the developmental specifiers for PTSD pertaining to the pediatric population that first appeared in the *DSM-III-R* (American Psychiatric Association 1987), it has been suggested that the *DSM-IV* criteria still lacked validity for younger children. In particular, it has been

pointed out that the *DSM-IV* criteria were based on data for individuals only age 15 and above (Scheeringa et al. 2011, 2012), and that a number of the criteria required a verbal description of experiences and internal states beyond the language capabilities of younger children (Scheeringa et al. 1995). Additionally, the *DSM-IV* Cluster C criteria for avoidance and numbing have been criticized as far too difficult for children to meet, as numbing and a sense of foreshortened future are difficult for preschool and school-age children to describe (Scheeringa et al. 2011), and children have a lesser ability to engage in avoidant behaviors as their caretakers dictate their routine and location (Pynoos et al. 2009). As a result, largely because of the Cluster C criteria, fewer children with significant posttraumatic symptoms met *DSM-IV* criteria for PTSD, leading to underestimates of its prevalence (Scheeringa et al. 1995; Scheeringa 2003).

In the *DSM-5* (American Psychiatric Association 2013a), changes have been made to the PTSD criteria for individuals aged 6 years and above, which includes school-age children and adolescents. Specifically, whereas the *DSM-IV* had three symptom clusters (B, C, and D) that include 17 possible symptoms, the *DSM-5* now has four symptom clusters (B, C, D, and E) that incorporate a total of 20 symptoms. Cluster A is now clearer in what defines a traumatic event, and how it can be experienced. Criterion A2 has also been removed due to its poor ability to predict the onset of PTSD. The former *DSM-IV* Cluster C has now been divided into two new categories: Avoidance (Cluster C) and Negative Cognitions and Mood (Cluster D). The new Cluster D has introduced symptoms of persistent negative beliefs about oneself and negative emotional states. Cluster E (alterations in arousal and reactivity) has also added the new symptom of reckless or self-destructive behavior. This has led to the observation that the new *DSM-5* criteria place a greater emphasis on the "fight" aspects of PTSD, rather than just "flight" as previous *DSM* editions did (American Psychiatric Association 2013b).

More important to the evaluation of young children is the creation of the developmental subtype of PTSD applicable to children aged 6 years and younger: Posttraumatic stress disorder for Children 6 Years and Younger. In comparison to the criteria for individuals above age 6, there are three symptom clusters instead of four, which include re-experiencing (Cluster B), avoidance and negative cognitions (Cluster C), and arousal (Cluster D). In addition, rather than emphasizing verbal descriptions by the patient of internal phenomena, the criteria are more rooted in behavioral manifestations of exposure to trauma. Notable specifiers for Cluster B are that spontaneous and intrusive memories as well as dissociative reactions may both be expressed through play reenactment in young children. Cluster C combines symptoms of both avoidance and negative cognitions, and in acknowledgement of the challenges of detecting these symptoms in young children, requires that only one symptom from either category be present for the diagnosis to be made. In Cluster D it is also specified that children may manifest extreme temper tantrums as a consequence of trauma.

FORENSIC IMPLICATIONS OF CHANGES TO THE *DSM-5*

What impact will the more developmentally informed *DSM-5* criteria have on the evaluation of PTSD in children and adolescents? Several studies that employed developmentally appropriate PTSD diagnostic criteria similar to those in the *DSM-5* found the rates of cases meeting full diagnostic criteria significantly increased when compared to the rates of diagnosis using *DSM-IV* criteria (Scheeringa et al. 2006; Meiser-Stedman et al. 2008; Iselin et al. 2010). It is expected that the incidence and prevalence in young children will now increase, given the criteria for posttraumatic stress disorder for Children 6 Years and Younger are specifically tailored to this age group, symptoms from clusters B and C will be easier to detect due to a greater emphasis on behaviors that can be observed or reported on by caregivers, and less difficulty in meeting criteria for avoidance and negative cognitions. It is less clear what the impact of the *DSM-5* criteria will be for school-age children and adolescents. One study has found that the use of the updated criteria led the prevalence of the PTSD diagnosis to decrease in an adult sample, likely due to the removal of actual or threatened death from natural causes from Cluster A, as well as the requirement for one symptom of avoidance for diagnosis due to the split of the former Cluster C (Kilpatrick et al. 2013). However, a more likely scenario is that the *DSM-5* criteria will have greater sensitivity for older children and adolescents than the *DSM-IV*, as the removal of the former Criterion A2 will likely allow more school-age children to meet Cluster A criteria, the wording of Cluster B has been loosened to allow a wider array of intrusion symptoms, and the inclusion of "reckless or self-destructive behavior" in Cluster E allows for a wider breadth of externalizing behaviors that adolescents, in particular, may engage in.

If the incidence and prevalence of PTSD increase due to the greater sensitivity of the *DSM-5* criteria, it is reasonable to hypothesize that courts will see a sharp increase in PTSD-based litigation in cases involving juveniles. This raises questions for how courts will employ the *DSM-5* criteria. Despite the American Psychiatric Association's warnings of reliance on the *DSM* in forensic settings, will courts continue to rely on it in making the diagnosis of PTSD as they have in the past for rendering judgments and measuring damages (Lubit et al. 2002)? Or will courts also take note of the increasing body of research suggesting posttraumatic symptoms in children and adolescents which do not meet full criteria for PTSD may still cause significant distress and impairment in functioning (Carrion et al. 2002)? This is especially relevant due to continued inclusion of the delayed onset specifier in the *DSM-5*, which acknowledges what research has illustrated is the time course of developing posttraumatic symptoms in children and adolescents, but could be used in the court setting to argue that a youth

is less impaired and suffering less than if the youth met full criteria.

Another question that has yet to be answered is what the specificity of the *DSM-5* criteria will be. Past criticism of the conceptualization of PTSD in the *DSM* has been that its symptoms overlap with multiple other diagnoses, including Major Depressive Disorder, anxiety disorders, disruptive behavioral disorders, and Attention Deficit/Hyperactivity Disorder. This is most true of the current Cluster D and to some degree in Cluster E. Data on the specificity of the new criteria for children and adolescents have not yet been published, and in the absence of this it is foreseeable that a common challenge to expert testimony will be whether another disorder can better account for symptoms in a juvenile than PTSD.

ADVANCES IN UNDERSTANDING POSTTRAUMATIC SYMPTOMS IN CHILDREN AND ADOLESCENTS

Epidemiology of exposure to trauma and PTSD

Research has demonstrated that many youth have been exposed to traumatic events. The Great Smoky Mountains Study demonstrated that in a community sample nearly 68% of children and adolescents ages 16 years and under surveyed had a lifetime exposure to a traumatic event, and that 37% had been exposed to more than one trauma (Copeland et al. 2007). Nearly 25% of the youth surveyed had been exposed to a violent trauma, while 11% had been exposed to sexual trauma. A further 33% of traumatic exposures were accounted for by physical illness, natural disasters, accidents, fire, and exposure to noxious agents. The National Child Traumatic Stress Network has additionally reported that 25% of youth have experienced a traumatic event by age 16 (Copeland-Linder 2008). Additionally, approximately 3 million cases of child abuse or neglect are reported in the United States each year (van der Kolk 2003), and national surveys have shown that 22% of adults have a childhood history of sexual abuse, and 30% have a history of physical abuse (Bremner 2003).

Though experiencing a trauma prior to the age of 16 is unfortunately not a rare event, it has been found that as in adults, it is a minority of children and adolescents who meet full diagnostic criteria for PTSD following a traumatic exposure—approximately 30% (Blom and Oberink 2012). Estimates of the prevalence of PTSD in the juvenile population have recently ranged from 0.5% to 9.2%, which is lower than the prevalence found in the adult population (Copeland et al. 2007; Cohen et al. 2010). However, in examining these data, it is important to keep in mind that the diagnosis of PTSD was made using *DSM-IV* criteria, and with more developmentally informed criteria of the *DSM-5*, prevalence rates will increase.

The likelihood of a child or adolescent developing posttraumatic symptoms and PTSD is also dependent on the type and severity of exposure. Natural disasters have been associated with lower PTSD rates of 0% to 5% in children (Salmon and Bryant 2002), though some studies have found that in more severe disasters rates can be as high as 95% (Gabbay et al. 2004). Physical injury has been associated with a rate of 23% (Aaron et al. 1999), while in cases of exposure to violent crime rates ranged from 27% to 33% (Arroyo and Eth 1985; Saigh 1991). A study of children in foster care found that 42% of those who had been physically abused developed PTSD (Dubner and Motta 1999). Among the highest rates of PTSD are those observed in children who have either witnessed their mother sexually assaulted or were exposed to parental homicide, estimated by one group to confer a PTSD rate of 100% (Pynoos and Nader 1988). Sexual abuse is also associated with high rates of PTSD, estimated by some to be as high as 90% (Salmon and Bryant 2002).

Developmental influences on posttraumatic symptoms

A cardinal feature of PTSD and posttraumatic symptoms in children and adolescents is that the manifestation of these symptoms is directly shaped by their age and developmental stage, including their capacity to encode and retrieve memories, their language capabilities, their ability to regulate their emotions, and their knowledge base (Salmon and Bryant 2002). In this context posttraumatic symptoms fall into four different age categories: preschool children, school-age children, adolescents, and adults.

The response of very young children to a traumatic event is primarily characterized by mood, behavioral, and anxiety symptoms, as they lack the language skills and emotional regulation of older children (Hagan 2005). Infants less than 12 months of age demonstrate increased crying, separation anxiety, irritability, an exaggerated startle response, and "freezing" (Veenema and Schroeder-Bruce 2002). In comparison, toddlers have greater disturbances of sleep, including nightmares and night terrors, show regression in behaviors and acquired skills, are more likely to have temper tantrums, and may demonstrate selective mutism (Veenema and Schroeder-Bruce 2002). Between the ages of 4 and 6 years, children may be more aggressive, can develop nocturnal enuresis, may regress in their use of language, and report somatic symptoms, such as headaches and stomachaches (Veenema and Schroeder-Bruce 2002). It has been suggested that younger children may be more susceptible to the posttraumatic symptom of re-experience (intrusive thoughts, images, or perceptions) because their memory is more visually and perceptually based (Fletcher 1996). The egocentrism found in young children can lead them to believe they were the cause of the traumatic event, which in turn can create stronger feelings of guilt than in older ages (Fletcher 1996; Rojas and Lee 2004). As mentioned earlier, preschool-age children also may not have the opportunity to engage in avoidant behaviors as their whereabouts and

activities are determined by their caretakers (Pynoos et al. 2009).

School-age children (age 6 to puberty) have a greater ability to have empathy for others who were affected by a traumatic event, and exhibit more symptoms in their interactions with others, including a fear of novel situations, social phobia, and repetitious traumatic play (Beauchesne et al. 2002; Veenema and Schroeder-Bruce 2002). Children above the age of 6 years may not demonstrate avoidant symptoms like younger children, but can develop incident-specific fears resembling phobias (Pynoos et al. 2009). Their presentation may also be significant for a lack of visual flashbacks or numbing symptoms (Cohen 1998). School-age children can also exhibit extended periods of re-experiencing that alternate with periods of avoidance and numbing, instead of both occurring simultaneously (Schwarz and Kowalski 1991).

Posttraumatic symptoms in adolescents most closely resemble those of adults, though with more prominent aggressive and risk-taking behaviors (substance use, high-risk sexual behaviors). Oppositional behaviors at home and school are commonly seen, as are school avoidance, depression, and anxiety (Pine and Cohen 2002; Veenema and Schroeder-Bruce 2002). Loss of interest in previously enjoyed activities, social withdrawal, eating disorders, poor emotion regulation, personality changes, self-destructive and impulsive behaviors, and impaired interpersonal functioning are also frequent posttraumatic behaviors in this age group (Pelcovitz et al. 1994; March et al. 1997). Exposure to prolonged or multiple traumas may present with primarily dissociative symptoms, including depersonalization, derealization, self-injurious behaviors, and intermittent angry and aggressive outbursts (Cohen 1998).

Natural history of PTSD in children and adolescents

The development and progression of posttraumatic symptoms in the pediatric population is variable and can be influenced by a number of factors. Rather than simply stemming from a single traumatic incident, accumulated evidence suggests the pathogenesis of PTSD is multifactorial, with contributions from genetic, psychological, neurobiological, and social factors. Three factors that have been correlated with an increased risk of developing PTSD in multiple studies are the severity of the trauma exposure, the length of time of the exposure, and the level of parental distress (Foy et al. 1996). It has been asserted that the most important of these three factors in preventing negative outcomes following trauma is the ability of a parent or guardian to cope with that same trauma, and provide a sense of security and safety to a child (Lyons 1987). A previous history of exposure to trauma, having experienced multiple traumas, poor social support, a history of previous psychiatric disorders, and a parental history of psychiatric disorders have also each been found to confer a higher risk of developing PTSD (Cohen et al. 2010). There has been controversy in the field regarding differing vulnerability to developing PTSD between genders, though current evidence suggests girls are at a higher risk due to differences in the types of trauma and differing coping strategies (Olff et al. 2007; Langeland and Olff 2008).

For those youth who develop full PTSD, it has been found in multiple studies that a significant number will continue to demonstrate sustained symptoms for extended periods that can last up to years (McFarlane 1987; Nader et al. 1990; La Greca et al. 1996; Scheeringa et al. 2005; Cohen et al. 2010), even with community treatment (Scheeringa et al. 2005). Though it has been demonstrated in the adult population that symptoms of PTSD may decrease or remit with time, this appears to occur less frequently or more slowly in youth. This has led some to argue that posttraumatic symptoms may persist for longer periods in children and are not likely to remit spontaneously (Pine and Cohen 2002).

Posttraumatic symptoms from a dimensional perspective

Though many individuals who are exposed to significant trauma do not go on to meet full diagnostic criteria for PTSD, it is known from studies with adults that many will demonstrate at least some posttraumatic symptoms (Rothbaum et al. 1992). Research from the adult population also indicated that developing subsyndromal PTSD is more common than meeting criteria for full PTSD, is associated with similar rates of help seeking, and is correlated with higher rates of psychopathology and impaired functioning (Stein et al. 1997; Copeland et al. 2007). Children and adolescents can also develop subthreshold symptoms, which have been found to create levels of distress and impairment that do not meaningfully differ from cases of full diagnostic PTSD (Carrion et al. 2002). Children in a large community sample who developed posttraumatic symptoms but did not meet full criteria for PTSD showed significant impairments in multiple domains, including disruption of important relationships, school problems, physical problems, and exacerbation of emotional problems (Copeland et al. 2007).

"High magnitude" events such as physical or sexual abuse may be more predictive of the diagnosis of PTSD, but the majority of posttraumatic symptoms in the pediatric population are the product of "low magnitude" events that occur more commonly, such as deaths or losses (Costello et al. 2002; Copeland et al. 2010). Though resulting from less "severe" traumas, the symptoms that develop from low magnitude events may be no less distressing or impairing for a child than those from high magnitude events. With this in mind PTSD cannot be viewed as a categorical entity, but is more appropriately seen as existing on a continuum in children and adolescents. The importance of this in the forensic setting is that courts may have a tendency to rely solely on the category of PTSD as defined by the *DSM*,

and thus risk underestimating a child's impairment and suffering when considering awards for damages.

Neurobiological effects of trauma in children

Numerous studies have found that psychological trauma can adversely affect normal neurodevelopmental processes and neurobiological functioning in children and adolescents. On a cellular level, trauma has been shown to affect multiple neurotransmitter systems. The norepinephrine system is a particularly important contributor to the autonomic stress response, with numerous studies demonstrating childhood abuse and neglect can lead to increased noradrenergic activity (De Bellis et al. 1999a,b; van der Kolk 2003). Children who have been exposed to trauma or diagnosed with PTSD have been found to have higher baseline epinephrine and dopamine levels than nonabused anxious children and controls (De Bellis et al. 1999b). It has also been shown that children with a history of traumatic exposure or PTSD have greater concentrations of urinary norepinephrine and dopamine than controls (De Bellis et al. 1999a,b). Additionally, alterations to serotonergic transmission may contribute to symptoms of hypervigilance, increased startle, impulsivity, and intrusive memories (Heim and Nemeroff 2009), while chronic stress is associated with decreased activity of gamma-aminobutyric acid (GABA) (Bremner et al. 2000; Bremner 2003). Finally, glutamate has also been suggested to play a role in the consolidation and maintenance of traumatic memories by mediating synaptic long-term potentiation, and may contribute to neuronal loss seen in the hippocampus and prefrontal cortex in adults with PTSD through excitotoxicity (Heim and Nemeroff 2009).

Genetic studies have identified several genes that are thought to be involved in the pathogenesis of PTSD. An excess of a polymorphism of a dopamine transporter gene, the SLC6A3 9 allele, has been found to be associated with an increased risk of PTSD (Segman et al. 2001), while specific haplotypes of the dopamine transporter (*DAT*) have been found to increase the risk of developing PTSD in preschoolers (Drury et al. 2013). Low expression of the S allele of the *5-HTTLPR* polymorphism in the *SLC6A4* serotonin transporter gene has also been associated with an increased risk of developing PTSD (Kilpatrick et al. 2007). A more recent study has also demonstrated that the S allele of the *5-HTTLPR* polymorphism is associated with a higher risk of developing PTSD secondary to childhood trauma in Americans of European descent (Xie et al. 2012). Investigation into the GABRA2 subunit of the $GABA_A$ receptor has pointed to an association between childhood trauma and GABRA2 single nucleotide polymorphisms (SNPs) in increasing the risk of developing PTSD, possibly through a greater posttraumatic anxiety response and facilitated traumatic memory encoding (Nelson et al. 2009).

The burgeoning field of epigenetics has increasingly illustrated the sustained functional changes to gene activity that exposure to trauma can create through DNA methylation. Animal models have found early life stressors can lead to methylation of genes that encode glucocorticoid receptors, leading to changes in hypothalamic–pituitary–adrenal (HPA) axis activity and observed behaviors (Yehuda and Bierer 2009). There is also evidence that epigenetic changes can be passed between generations, which has led to a hypothesis that maternal PTSD can increase the risk of PTSD in their children through epigenetic mechanisms (Yehuda and Bierer 2009). Higher cytosine methylation of the $NR3C1\text{-}1_F$ promoter for the glucocorticoid receptor gene has recently been reported to be found in individuals exposed to childhood abuse and early traumatic events (Yehuda et al. 2014). Additionally, the *FKBP5* glucocorticoid receptor co-chaperone has been found to predict the onset of adult PTSD symptoms following a trauma in patients with a history of childhood abuse, which more recently was determined to be associated with DNA demethylation of functional glucocorticoid response elements of *FKBP5* (Binder et al. 2008; Klengel et al. 2014). DNA methylation of the *ID3*, *GRIN1*, and *TPPP* genes following childhood trauma has also been correlated with an increased risk of depression in children (Weder et al. 2014).

Trauma also induces changes to the regions of the brain mediating the fear and stress response, including the HPA axis, amygdala, hippocampus, corpus callosum, and prefrontal cortex (Heim and Nemeroff 2009). The activation of the HPA axis by a stressor ultimately leads to a downstream release of glucocorticoids, specifically cortisol, which have been a source of controversy in the study of pediatric PTSD. Studies of adults with PTSD have shown decreased cortisol levels (Yehuda 2006), while most studies of traumatized children and adolescents have shown elevated levels of cortisol (De Bellis et al. 1999a; Cicchetti and Rogosch 2001; Gunnar et al. 2001). In reconciling these two seemingly disparate findings, it has been proposed that following a trauma, children and adolescents experience an increase in cortisol levels, which will gradually decrease as time passes due to a compensatory downregulation of an overly active HPA axis (van der Kolk 2003). It has also been posited that stress in early life may result in a persistent hypersecretion of corticotropin-releasing factor (CRF) in the central nervous system, which contributes to an increased reactivity to stress as an adult (Heim and Nemeroff 1999).

Neuroimaging

As the field of neuroradiology has advanced, courts have increasingly turned to neuroimaging as a means of illustrating observable neurological changes caused by trauma. The forensic importance of this lies in the observation that juries are more likely to award damages for physical disorders rather than those that are purely psychiatric (Lubit et al. 2002). Children and adolescents with a history of maltreatment have been observed on magnetic resonance

imaging to have pituitary volumes that are significantly larger than controls (Thomas and De Bellis 2004). In contrast to imaging studies of traumatized adults which have demonstrated reduced volume of the hippocampus (Bremner 2003; Rinne-Albers et al. 2013), in youth exposed to trauma the majority of studies have shown no hippocampal volume changes (Rinne-Albers et al. 2013). This has led to the theory that prolonged and excessive exposure to glucocorticoids that results from trauma is neurotoxic and leads to a gradual reduction in the volume of the hippocampus over time, which becomes more prominent on imaging as the child ages (van der Kolk 2003; Carrion and Kletter 2012; Rinne-Albers et al. 2013). Multiple studies have also shown reductions in total cerebral volume in youth with a history of trauma, suggestive of diffuse neurological damage (Rinne-Albers et al. 2013). This is a finding that appears to be unique to children and adolescents and has not been reported in adult samples.

Specific types of trauma have been found to affect particular areas of the brains of children and adolescents, depending on the sensory modality of the trauma exposure. For example, in young adults who witnessed domestic violence or were sexually abused, changes in the visual pathways of the brain have been observed (Tomoda et al. 2009; Choi et al. 2012). In contrast, those subjects who were exposed to verbal abuse had observable changes in gray matter volume in areas of auditory processing (Tomoda et al. 2009). Seeing a trauma leads to changes in the visual cortex, while hearing trauma alters the auditory cortex.

One of the most replicated findings from structural imaging of PTSD in youth is a reduced cross-sectional area and connectivity of the corpus callosum (Rinne-Albers et al. 2013), not only in comparison to controls, but also to other psychiatric disorders (Teicher et al. 2004). Additionally, abnormalities in neuronal metabolism in the medial prefrontal cortex have been demonstrated on proton magnetic resonance spectroscopy (De Bellis et al. 2000), as have differences in the activity of the frontal and prefrontal cortex on functional magnetic resonance imaging in traumatized adolescents (Carrion et al. 2008).

COMORBIDITIES ASSOCIATED WITH PTSD

In addition to posttraumatic symptoms, traumatic exposure is associated with high rates of psychiatric comorbidity in children and adolescents. Community samples have demonstrated that traumatized children have rates of psychiatric disorders nearly twice that of nontraumatized counterparts (Copeland et al. 2007). Significantly higher rates of dysthymia and major depressive disorder have been found in youths with PTSD, as well as a high prevalence of generalized anxiety disorder, panic disorder, and specific phobias (Linning and Kearney 2004). Elevated rates of separation anxiety, attention deficit/hyperactivity disorder, and oppositional defiant disorder have also been demonstrated in abused children (Ackerman et al. 1998). Childhood sexual abuse has been found to be predictive of conduct disorder and adult substance abuse (Fergusson et al. 1996), and has additionally been associated with an increased risk of adolescent suicide attempts (Brown et al. 1999). It has been estimated that as many as 20% of all adolescent suicide attempts are related to sexual abuse (Brent et al. 2002). The development of borderline personality disorder has also been associated with a history of sexual trauma (Herman et al. 1992).

Psychiatric comorbidity is but one type of negative outcome of PTSD for children. Behavioral and cognitive deficits have been attributed to experiencing chronic trauma, including poor emotional regulation, deficits in learning and memory, and social difficulties (van der Kolk 2003). A poor sense of self, distorted body image, poor impulse control, and distrust and suspicion of others are also known sequelae of trauma (van der Kolk 2003). The hypervigilance against impending threats that children with PTSD manifest may lead to disturbances in attention that can be mistaken for ADHD (van der Kolk 2003). It has also been shown that children with PTSD perform worse academically than nontraumatized peers (Saigh et al. 1997). It has even been found that adults with a history of childhood trauma are at a higher risk of negative medical outcomes, including ischemic heart disease, cancer, liver disease, and chronic lung disease (Felitti et al. 1998).

FORENSIC EVALUATION OF PTSD IN CHILDREN AND ADOLESCENTS

The general purpose of the evaluation of trauma in a forensic setting is to evaluate, define, and determine the extent of psychological damage and suffering the person is experiencing due to a traumatic exposure, and to inform the court as to prognosis and recommendations for treatment. This does not necessarily mean the primary aim of the evaluation should be to diagnose or rule out PTSD, for as was previously discussed, subsyndromal posttraumatic symptoms are still quite impairing and are associated with high rates of psychiatric comorbidity. With children and adolescents in particular, there is a need to provide an evaluation that goes beyond the diagnosis of PTSD as defined by the *DSM-5*, and paint a broader picture of their functioning and developmental trajectory. In addressing these points, issues that must be resolved in the mind of the evaluator include whether the trauma in question was the immediate cause of distress and dysfunction, what the relative weight of comorbid psychiatric disorders is in affecting the individual's functioning and emotional state, and to what extent resilience factors or ongoing stressors may be modulating the presentation of posttraumatic symptoms. In addition to a full psychiatric history, necessary components of the evaluation are outlined in Table 42.1. It is vital that the evaluator assess the reliability of the information obtained, and the use of more sources of data and objective measures of symptoms may help to ensure that reliability.

Table 42.1 Components of the forensic psychiatric evaluation of trauma in children and adolescents

1. Diagnosis
2. Symptom severity
3. The causative trauma that led to psychopathology
4. Identification of any preexisting psychiatric conditions
5. Psychiatric comorbidity that developed following the trauma
6. Prognosis
7. Treatment recommendations

The forensic interview

THE PARENT INTERVIEW

With any pediatric forensic case it is recommended to interview the child's parents or guardians first when possible, with the notable exceptions of when it is the guardian that is accused of victimizing the child or there is suspicion that the guardian may be motivated to protect a perpetrator. Relevant past psychosocial, family, medical, psychiatric, and developmental history should be reviewed, and consent can be obtained to access previous records and to speak to collateral sources. A focus of the interview should be on the child's functioning prior to the stressor and subsequent changes (Lubit et al. 2002). In particular, questions about the quality of the child's play, the child's social interactions, and the child's academic performance must be asked. The evaluator should also explore the caretaker's perception of the child's ability to express positive emotions, the presence of negative beliefs, cognitions, and emotions, and reckless and self-destructive behaviors. With regard to this last point, the intent of reckless or self-destructive behavior must be understood in order to differentiate it from an act of impulsivity or rule-breaking behaviors, such as could be seen in ADHD or conduct disorder. For preschoolers, potential symptoms of avoidance, traumatic re-enactment in play, and frequency of temper tantrums must be investigated. The aforementioned finding that parental distress and support after a trauma have direct impacts on the course and outcome of posttraumatic symptoms also requires the evaluator to determine the caretaker's degree of functioning (Salmon and Bryant 2002).

It is vitally important to remember that parents have a tendency to under-report PTSD symptoms, and while they are good reporters of externalizing behaviors, they are known to be poor reporters of internalizing symptoms in their children (Lubit et al. 2002). Studies have demonstrated that when a parent's report of symptoms was used alone, it significantly underestimated the child's true symptom load (Scheeringa et al. 2006).

THE CHILD AND ADOLESCENT INTERVIEW

It is essential that the forensic interview be tailored to the emotional and cognitive developmental stage of the child. This has broad implications in determining their ability to relate details of the event, characterizing the developmental context in which their symptoms are occurring, discerning pathological from nonpathological behaviors, and estimating their ability to provide accurate testimony.

Children and adolescents may be reluctant to speak about their trauma for obvious reasons: difficulty describing what happened (particularly for younger children), feelings of embarrassment, shame, or guilt, and avoidance to prevent distress. Evaluators may avoid asking direct questions about the trauma for fear of upsetting the child (Lubit et al. 2002; Salmon et al. 2002). However, a necessary part of the interview is to engage with the child on aspects of the traumatic event in order to adequately evaluate and understand the child's symptoms and response to the incident (Pynoos and Eth 1986; Wolfe et al. 1994). This process can be made easier by forming a rapport with the child and helping the child feel at ease. This may include expressing empathy and regret for the discomfort the child may have, making efforts to minimize distress and fatigue from the interview, explaining the nature of the evaluation, and leaving time at the end of the interview to explore their impressions and thoughts about the evaluation (Lubit et al. 2002).

With young children, their ability to participate in an interview will not only be influenced by their reluctance to speak about the event, but also their developmental, cognitive, and language limitations. Establishing the child's understanding of the difference between truth, lies, and imagination is important for gauging the child's reliability.

With both children and adolescents, open-ended questions should generally be asked first, followed by more specific questions. Use of play, drawing pictures, storytelling, and sandwork are techniques that can be employed in enhancing communication with younger children (Pynoos and Eth 1986; Salmon et al. 2002). Traumatic play tends to be repetitive and simple and lacks the elaboration and imagination seen with children who have not experienced trauma. It is also often not enjoyable and does not relieve anxiety. The child may act out the trauma, taking the role of the aggressor, or incorporate undoing or denial into his or her retelling of the incident (Terr 1981). Drawing may help children give more detailed verbal reports by providing retrieval cues and structure to their narrative. Drawing may also reduce the social and emotional demands of the evaluation for the child (Gross and Hayne 1998).

The use of anatomical dolls in the evaluation of young victims of sexual abuse is controversial, and has been criticized as being overly suggestive and encouraging of fantasy (Ceci and Bruck 1995). The use of toys in the evaluation to re-create the trauma has also been described as a distraction that can prevent a young child from recalling or reporting details of the trauma, as they may associate more generally with play than with the details of an event (DeLoache and Marzolf 1995).

COLLATERAL REPORTS AND PSYCHOLOGICAL TESTING

The forensic evaluation of children and adolescents following an alleged trauma is recommended to involve multiple means of assessment and sources of collateral information in addition to the primary interview. What other individuals have said about the event to the child and what other interviews have been conducted must be examined to search for possible distortions of the child's account. In addition to the parent interview, collateral reports can be gathered from other family members (grandparents, siblings), teachers, school counselors, child protective services, the child's pediatrician, and past therapists or psychiatrists. Documents that should be reviewed include available medical, psychiatric, and therapy records, police reports, and media accounts (Lubit et al. 2002).

It has been asserted that evaluators often use unstructured assessments in forensic evaluations of PTSD that are not empirically supported, and therefore may be of limited reliability (Koch et al. 2005). Psychological testing may be beneficial at times for evaluating current cognitive functioning or comparing current functioning to previous cognitive baseline, as PTSD is known to affect memory, learning, and attention (Lubit et al. 2002). The Wechsler Intelligence Scale for Children, 4th edition (WISC-IV) is commonly used to assess intellectual functioning, and the Woodcock Johnson Tests of Achievement, 3rd edition, provides measures of math and language abilities, as well as visuospatial functioning. Memory can be tested with the Wide Range Assessment of Memory and Learning (WRAML), or the California Verbal Learning Test—Children's Version (CVLT-C) (Lubit et al. 2002). Tests to consider in assessing emotional and personality functioning include the Minnesota Multiphasic Personality Inventory-Adolescent Version (MMPI-A) and Personality Inventory for Children (PIC).

One rating scale that has been developed by the American Psychiatric Association (APA) using *DSM-5* criteria for assessing PTSD in school-age children is the National Stressful Events Survey PTSD Short Scale (NSESSS) (APA 2013c). It is a nine-item measure for children aged 11–17 years who have been diagnosed with PTSD or demonstrate clinically significant posttraumatic symptoms, and used as a self-report of symptoms in the prior 7 days. It is used to establish baseline symptoms as well as to track these symptoms over time. Further measures for PTSD symptoms in children and adolescents using *DSM-5* criteria are in development and are expected to be released in the near future.

Accuracy of testimony

An area of potential scrutiny in pediatric forensic cases is the accuracy of the child's report and testimony. Despite the cognitive, language, and memory limitations that children may possess, they have the ability to be reliable witnesses. It has been generally found that children perform as well as adults in recalling the core aspects of a memory, though they do less well on the peripheral details (Meyer 1997). When children make errors in their testimony, these are more likely to be a failure to report an event that did happen, rather than falsely report one that did not happen (Flin and Spencer 1995). Prior to middle childhood, children lack the cognitive strategies to retrieve memories spontaneously. They are reliant on prompts from adults including questions and repeating features of the event (Salmon and Bryant 2002). Without this structure provided by adults, the details are often not able to be accessed by the child. However, this also can be an avenue to the contamination of the memory, as repeated questions can compel a child to alter his or her response or confabulate.

The degree of suggestibility that a child or adolescent demonstrates is a frequent challenge to the child's testimony. There are unfortunately multiple examples of cases where suggestibility has led to false accusations of sexual abuse or trauma (Kulkofsky and London 2010). Age has been found to be the best predictor of suggestibility, with younger children consistently found to be more suggestible than older children or adults (Ceci and Bruck 1993). Fatigue and stress can also increase suggestibility (Goodman et al. 1999). Parents who are overly anxious or have histrionic traits may overreact to an innocent statement that a child made, which can lead to inaccurate recollections and false accusations (Lubit et al. 2002). Children can also unintentionally distort reality to avoid a feared punishment, avoid embarrassment, gain attention or sympathy, or even to be vindictive (Bernet 1993). Children and adolescents additionally may deny a trauma happened to protect an abuser, or to avoid feelings of embarrassment or guilt. Errors evaluators make while interviewing children that lead to distortions in testimony will be discussed further below.

Although there is a very real danger the recall of a suggestible child may be inadvertently altered, there is also evidence that children's memories can be resistant to making false accusations, even after leading questions have been posed. In studies in which children had undergone routine medical procedures, leading questions were asked. These children were not likely to make false reports of abuse even after a year (Goodman et al. 1991a,b; Saywitz et al 1991). Four-year-old children were also found to be resistant to alleging abuse, even when prompted by an evaluator to do so (Rudy and Goodman 1991; Flin and Spencer 1995).

Evaluation of malingering

In every forensic evaluation the issue of malingering should be examined. There is, however, little evidence that children will maintain symptoms in order to gain compensation (Kulkofsky and London 2010), and younger children are not motivated by financial rewards to change their account. Motivations change as a child ages, with adolescents more likely to present false information for secondary gain (Lubit et al. 2002). Parents may encourage their children to fabricate a traumatic experience for financial gain, or in cases of custody disputes to gain an advantage for their petition

or for revenge. Symptoms that raise suspicion for malingering include those that draw attention, are exaggerated, or may not fit in a particular diagnostic category. There may be inconsistency between the child's reported loss of function and what the child is actually able to do, pointing to the value of observing the child in numerous settings, if possible. For example, claims may be made that the child is unable to function in school, despite continued participation in sports and other activities without difficulty. Additional presentations that are suggestive of malingering include an eagerness to discuss past trauma, an attitude of entitlement, low observed anxiety and depression in the context of high reported symptoms, and unrealistic claims of what constituted a trauma (Ingram et al. 2012). In testing the hypothesis that a child or adolescent may be malingering, Lubit et al. have suggested techniques such as asking about symptoms that are not part of PTSD, mentioning an atypical symptom in ear shot to see if it is reported by the patient, and making a loud noise to gauge the startle response (Lubit et al. 2002). Caution must be employed in pursuing a diagnosis of malingering. Children may have difficulty with sequences of events, details of an incident, or differentiating between episodes of a repeated event. This can resemble attempts to fabricate information, when, in actuality, the response may be developmentally appropriate.

Pitfalls to avoid

It has been suggested that the greatest errors forensic evaluators of pediatric PTSD tend to make include a failure to consider other stressors, misuse of psychiatric diagnoses, failure to consider other diagnoses, inattention to the credibility of reports of trauma, and ignoring the subjective nature of PTSD (Kulkofsky and London 2010). A full history may not be taken, which may lead the evaluator to overlook past traumas that occurred prior to the one in question as the source of posttraumatic symptoms. A poor history may also lead an evaluator to miss preexisting psychopathology unrelated to trauma. Malingering is also often not considered in children. Psychiatrists additionally often fail to appreciate that courts hesitate in accepting the diagnosis of PTSD based on the interview alone, and do not sufficiently use psychological testing and collateral reports. Finally, evaluators may not strictly follow *DSM* criteria, and may attempt to attribute PTSD to stressors that do not meet Criteria A.

With regard to contaminating a young child's testimony, the primary means by which children's accounts have been altered is through an evaluator's use of leading questions, which presume certain events occurred ("That's when he touched you in your private parts, right?"). Interviewer bias plays a key role in suggestibility as well, and can be expressed through positive and negative reinforcement, creating negative or accusatory emotional tone in the evaluation, repeating questions until a desired answer is given, and using peer or parental pressure in the interview (Kulkofsky and London 2010). Repeatedly asking the same question in the absence of interviewer bias can also unintentionally lead a child to change his or her answer as the child may fear that his or her previous answer may be "wrong " (Lubit et al. 2002). Specific and direct questioning in young children may lead them to feel that they must respond, and increases the risk that they will not report accurate information (Poole and Lamb 1998). Use of drawing can be of help in attaining a description of events but can also potentially introduce errors into children's accounts, as evaluators can inadvertently suggest inaccurate information during the interview (Bruck et al. 2000).

To guard against suggestive interviews with young children, using open-ended questions and avoiding the repetition of questions is recommended. An effort should be made to maintain a neutral emotional tone during the evaluation. In addition, the child should be allowed to describe the trauma in his or her own words. Finally, a structured interview protocol has been created by the National Institute of Child Health and Human Development (NICHD) for forensic evaluators, which is specifically designed to reduce suggestibility (Orbach et al. 2000).

Though neuroimaging can be a powerful and persuasive tool in the courtroom, there are clear limitations to what information it can convey. As it is a rare occurrence that a child or adolescent will have previous imaging to compare post-trauma studies to, the opposing side may assert that abnormalities seen on imaging may not be related to a stressor at all, and instead are due to a pre-existing condition (Bottalico and Bruni 2012). Due to the high rates of comorbidity of PTSD with other disorders, it may be difficult to differentiate between neuroanatomical changes caused by an anxiety or mood disorder from those that are associated with PTSD. Additionally, as findings from neuroimaging studies are from aggregate data compiled from multiple subjects, each with differing brain activity, a challenge can be whether a particular research finding is applicable to a specific individual. The field of neuroimaging is simply not yet at a stage where a definitive answer can be given to that question.

SUMMARY

Alan Stone has asserted that "No diagnosis in the history of American psychiatry has had a more dramatic and pervasive impact on law and social justice than posttraumatic stress disorder" (Stone 1993). Though it is a minority of youth who will develop full diagnostic PTSD following exposure to trauma, we now know how harmful and debilitating subthreshold symptoms can be, and that posttraumatic symptoms as defined by the *DSM* are but one type of sequelae children may experience. In approaching evaluations of traumatized and abused youth, child and forensic psychiatrists must incorporate knowledge of development, neurobiology, family dynamics, updates to

the *DSM-5*, and the nature and course of PTSD in different age groups. The evaluation must involve not only forensic interviews of the youth and their caretakers, but also collateral sources of information from schools, legal authorities, psychological testing, and past psychiatric and medical records. Though there is a danger of contaminating a youth's recollection of events through improper interviewing, a well-prepared and careful evaluation and application of appropriate interviewing techniques are known to mitigate this risk, allowing a child to provide accurate and reliable testimony. For the large proportion of children and adolescents who are exposed to trauma prior to adulthood, the forensic evaluator plays an integral role not only in helping them receive the justice and compensation they deserve, but also in guiding them toward treatment, and educating attorneys and the courts as to the effects of trauma in this vulnerable population.

SUMMARY KEY POINTS

- The *DSM-5* criteria for posttraumatic stress disorder is most developmentally appropriate to date for children and adolescents.
- The incidence and prevalence of PTSD in young children in particular is expected to increase using the new criteria, which in turn is likely to increase PTSD-based litigation.
- Posttraumatic symptoms that do not meet full criteria for PTSD may still cause significant distress and impairment for many youth.
- Children will manifest posttraumatic symptoms differently depending on their age and developmental stage.
- Forensic evaluations of traumatized youth must incorporate information from multiple sources, outside of child and caretaker interviews, which may include psychological testing, medical and psychiatric records, and school reports.
- Care must be taken to acknowledge and avoid multiple pitfalls that are specific to performing forensic evaluations in the pediatric population.

Forensic aspects of suicide and homicide in children and adolescents

PETER ASH

INTRODUCTION

Homicide and suicide are, respectively, the second and third leading causes of death for adolescents aged 15–19 (National Center for Health Statistics 2014). Society often expects psychiatry to be able to accurately predict and effectively prevent suicide and homicide, despite realistic limitations in these areas. In a treatment context, clinicians must recognize the children and adolescents most at risk for violence and take appropriate steps. In a forensic context, cases of homicide and suicide are frequently the focus of court scrutiny, and forensic psychiatrists frequently play a role in the adjudication of such cases.

SUICIDE

Epidemiology and demographics

Adolescent suicide rates have been quite variable, tripling from 1955 to 1979 (Brent et al. 1988), then increasing slowly to a peak in 1991, before falling back to the rates of the 1980s, although rates have been increasing slowly since 2007 (Centers for Disease Control and Prevention 2015). It is unclear why adolescent suicide rates increased through the early 1990s and then declined, although these changes roughly parallel the directions of changes in youth homicide rates and firearm-related deaths (see Figure 43.1).

The Centers for Disease Control and Prevention (CDC) maintains a number of publicly accessible online databases, some of which can be very useful for forensic psychiatrists. The CDC's WISQARS database (CDC 2015) contains national data regarding fatal injury, including accidents, suicide, and homicide. Querying WISQARS reveals a 2013 suicide rate of 8.6/100,000 for 15- to 19-year-olds representing 1748 suicides in the United States (CDC 2015). Rates for younger adolescents were much lower, averaging about one-sixth of the older adolescent rates, and rates for preadolescents are much lower still, with an average of only five deaths per year in children under age 10 classified as suicides in the decade ending in 2013. In 2013, male adolescents were about three times as likely to commit suicide as females. This difference is explained, in part, by the means of suicide employed: teenage males tend to use more lethal methods, such as firearms and hanging, rather than less dangerous methods often used by females, such as poisoning (e.g., carbon monoxide or pill overdose) or wrist cutting. By contrast, the most common method among unsuccessful attempts is overdose, followed by wrist cutting (Holinger 1990; Low and Andrews 1990).

Historically, white adolescents have been about twice as likely as African Americans to commit suicide. In a study comparing adolescent suicide victims to a control group of nonsuicidal adolescents, there was no significant difference found in socioeconomic status (Shaffer and Craft 1999). Gay and lesbian youth are at increased risk for suicide (Stone et al. 2014), but this appears to be a consequence of increased risk for mood disorder and other mental health problems which are risk factors for suicide, rather than related directly to stressors of stigmatization (Shaffer et al. 1995).

In adolescents, suicidal ideation and attempts are fairly common. The Youth Risk Behavior Survey (YRBS) is an annual survey of adolescent risky behavior conducted by the CDC. The 2013 YRBS found that 17% of high school students had seriously considered suicide in the previous 12 months, 13.6% had made a plan, 8% had made a suicide attempt, and 2.7% had made an attempt of sufficient severity as to receive medical attention (Kann et al. 2014). Girls had about double the rates of boys in each of these categories. Although completed suicide is rare in prepubertal children, self-destructive thoughts and behavior are frequent in this young age group, and those that express suicidal ideation are more likely to have symptoms of psychiatric illness and are more likely to evidence suicidal behavior later in adolescence (Dervic et al. 2008; Pfeffer 2003).

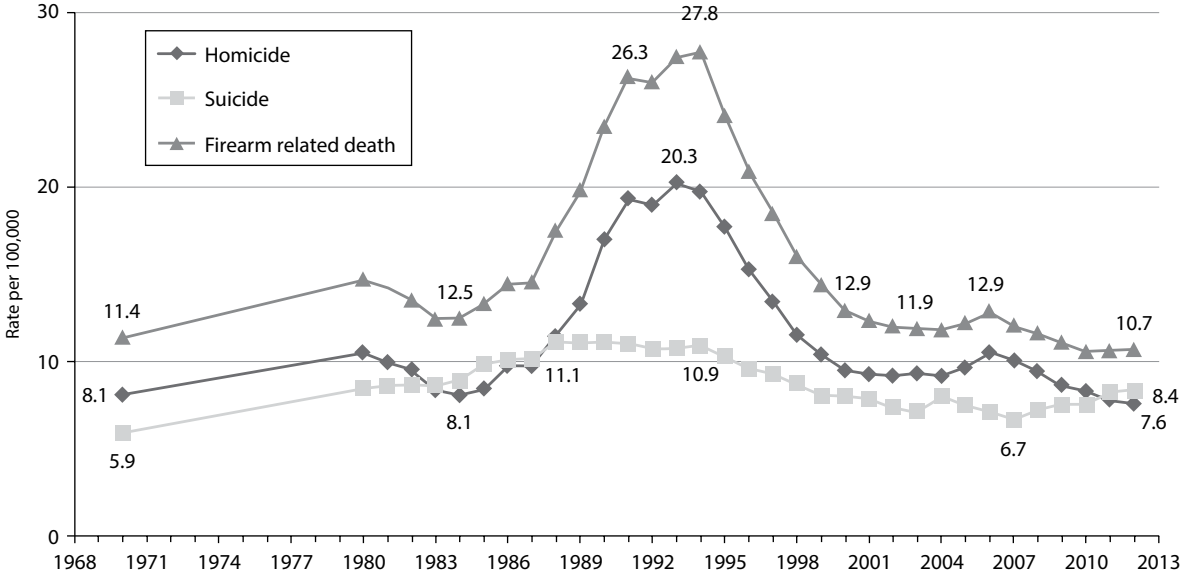

Figure 43.1 Rates (per 100,000) for homicide, suicide, and firearm-related deaths of youth ages 15–19, selected years 1970–2012. (Data for 1970–1980: National Center for Health Statistics. [2002] *Health United States, 2002 With Chartbook on Trends in the Health of Americans*. National Center for Health Statistics. Tables 46, 47, and 48; data for 1995–2012: Centers for Disease Control and Prevention. *Web-based Injury Statistics Query and Reporting System [WISQARS]* [Online]. [2014]. National Center for Injury Prevention and Control, Centers for Disease Control and Prevention [producer]. Available at www.cdc.gov/injury/wisqars/fatal.html. Modified from chart source: Child Trends Databank [2015]. With permission.)

Risk factors and precipitants

Predicting suicide in an individual case is clouded by the fact that completed suicide is rare when compared with clinical presentations of suicidal ideation and suicide attempts. The rate of suicidal ideation in the 2013 YRBS discussed above is over 2000 times the rate of completed suicide (17% ÷ 0.008%). This high ratio indicates the low specificity of using ideation as a risk factor for completed suicide, which very much complicates risk assessment. Similar to the adult population, there are no studies that identify factors that allow a clinician to accurately predict which adolescents will commit suicide. Research has therefore focused on risk factors; those characteristics that appear at greater frequency in the population of those who have completed suicide when compared to other groups. Because many youth who complete suicide were not previously in treatment, research assessment of those who have committed suicide is most commonly done utilizing psychological autopsy. The 1990s saw a great deal of research elucidating risk factors for adolescent suicide. The suicide risk factor literature is complex, reflecting changing rates and patterns of suicide, significant age and sex differences, and different sample populations, comparison groups, and statistical methods. Many different factors have been identified as increasing risk when compared to normal subjects (American Academy of Child and Adolescent Psychiatry 2001; Gould et al. 2003; Dervic et al. 2008; Cash and Bridge 2009). Risk factors commonly cited in the literature appear in Table 43.1.

Table 43.1 Summary of leading risk factors

Individual factors
Previous suicide attempt
High intent/lethality of method
Psychopathology
Major depression
Helplessness and hopelessness
Bipolar disorder
Substance abuse comorbid with other psychopathology
Schizophrenia
Conduct or personality disorder, especially with impulsive characteristics
Demographic factors
Over age 14, risk increases with age
Male
White
Unwed adolescent with unwanted pregnancy
Family and environmental factors
Firearm in the home
Family pathology/discord
Abuse (physical or sexual)
History of violence
Recent stressors
Separation
Arrest/legal problems

Clinically, suicidal ideation, especially when coupled with a plan involving lethal means, or a recent attempt, is most often the trigger to a judgment of imminent danger requiring hospitalization. In psychological autopsy studies, previous attempts have long been found to be the strongest risk factor for boys, increasing the risk about 30 times over the normal population (Shaffer et al. 1996; Brent et al. 1999).

Two well-controlled studies (Brent et al. 1993b; Shaffer et al. 1996) both found high rates of psychiatric disorder, around 90%, in suicide completers, a finding that has held up in later studies (Cash and Bridge 2009). Major depressive disorder was the most prominent finding and poses the most risk. In the absence of clear psychopathology, suicide is associated with recent legal or discipline problems, interpersonal loss or conflicts, and the presence of firearms (Brent et al. 1993c; Cash and Bridge 2009). Axis II psychopathology is also found in many suicide completers. Some biological factors have been implicated, including the serotonergic system (Zalsman et al. 2011) and brain structure (Lippard et al. 2014). Family stressors listed in Table 43.1 constitute a second domain of risk factors for suicide. Beyond the family, environmental factors can influence suicidality. Personal contact with a suicide victim can lead to increased suicidal behavior, such as a cluster of incidents in a single community.

Many, but by no means all, suicides have a clearly identified precipitant, although a stressor in the absence of preexisting vulnerability likely does not cause suicide. Marttunen et al. (1993) identified a precipitant in 70% of a series of cases. Of those, half the precipitants occurred in the 24 hours preceding the suicide. Interpersonal problems, particularly separations, were the most common stressor. Of particular interest to forensic psychiatrists, arrest is a risk factor as a precipitant for suicide. In one study (Brent et al. 1993a), among the minority of adolescents who did not appear to have a psychiatric disorder, 43% had legal problems or discipline in the prior year.

Firearms are the most common method of committing suicide, and firearm access is an independent risk factor for adolescent suicide (Simonetti et al. 2015).

Assessment

Asking about depressive feelings and symptoms, suicidal ideation, and a history of attempts of self-harm should be a routine part of the initial evaluation of an adolescent or depressed child. In a malpractice case arising from a suicide, liability often turns on the adequacy of the suicide assessment. The assessment of suicidality generally focuses on the risk and protective factors identified above, and information from collateral sources such as parents and prior psychiatric records, when available, should be sought. Information from sources other than the identified patient should be considered seriously, as many youth with suicidal ideation may be reluctant to reveal their true feelings. A patient with a constellation of risk factors that does not include moderate to high intent or a recent suicide attempt generally does not require hospitalization on the grounds of suicidality because of the low power of such risk factors to predict the short-term future (although the youth's condition may warrant hospitalization on other grounds). The threshold issue is generally the presence of thinking about suicide or a recent attempt. Characteristics of attempts with high intent include lethality of method, gestures of saying "goodbye," such as giving away belongings, leaving a note, writing a will, and efforts to minimize or prevent discovery and rescue. The American Academy of Child and Adolescent Psychiatry has developed practice parameters for the assessment and treatment of suicidal behaviors (American Academy of Child and Adolescent Psychiatry 2001). Assessing the severity of suicidal ideation involves evaluating the nature of the youngster's thinking, whether the youngster has formulated a plan, the lethality of the plan, access to means, the youth's level of helplessness and hopelessness, and the details of any recent attempts. Interviews with family members and reviewing medical and school records may provide useful additional data. Once suicidal thinking has been identified, other risk factors take on added significance. It is important to pay attention to the dynamic factors, including which stressors have precipitated suicidal thinking or past attempts, and to assess the likelihood of such stressors recurring.

In evaluating protective factors, the clinician needs to look to the nature of available social support, especially from the family, internal resistances to suicide, such as religious objections, the extent to which stressors in the environment can be ameliorated, and the usefulness of the family in monitoring the youngster's thinking and behavior.

Treatment

Once significant suicide risk has been identified, treatment encompasses four major components: protection of the patient, continuing assessment of risk, ameliorating risk factors, and enhancing protective factors.

Protection of the patient is the first consideration. In outpatient treatment, it is important to involve the family in monitoring and supporting the patient, making firearms and lethal medications unavailable to the patient, and forging an alliance for supporting continuing treatment. The family must feel comfortable with the outpatient plan and agree to accept some of the responsibility for the patient's safety. One important method of assessing a patient's capacity to be treated as an outpatient is to simply ask what he or she would do if stressors recurred. No-suicide contracts are often used in treatment, but there is little evidence that such contracts provide much protection. If the outpatient plan does not appear likely to manage the suicide risk, the youth is generally hospitalized. Involuntary hospitalization may be required if parents refuse voluntary admission of their child. While hospitalized, an appropriate level of observation should be maintained. During periods of active suicidal or self-destructive ideation, patients may require continual monitoring until such impulses have resolved.

Treatment should include addressing and diminishing those characteristics that constitute dynamic risk factors, including the treatment of underlying psychopathology. In the past 10 years, several multisite studies have provided evidence that a combination of psychotherapy and medication is the preferred approach in treating suicidal adolescents. The Treatment for Adolescents with Depression Study (TADS) showed that a combination of fluoxetine and cognitive behavioral therapy (CBT) resulted in significant improvement in 71% of moderately to severely depressed adolescents (March et al. 2004). Drug treatment alone and CBT alone also showed positive, although somewhat weaker, effects. Suicidal thinking was also significantly reduced in all groups, including the placebo group, although treatment effects in comparison to placebo were weak for this symptom. The Treatment of Adolescent Suicide Attempters Study (TASA) suggested that adolescent suicide attempters treated with psychotherapy and medication improved at about the same rate as nonsuicidal depressed adolescents (Vitiello et al. 2009).

Psychotherapy plays an important role in treatment in providing information about continuing risk, delineating how the youth thinks about suicide, addressing underlying psychopathology, helping the adolescent cope with such stressors as may be present, and enhancing protective factors such as more adaptive defenses or coping strategies. Some factors are best dealt with in a family context, including ameliorating disruptive or stressful family patterns and eliminating access to firearms. Unfortunately, parental compliance with a recommendation to remove firearms is fairly low, even when parents are provided with considerable information about the risks and strong recommendations (Brent et al. 2000). Working to increase family support is an important component of enhancing protective factors.

Legal considerations

In an outpatient treatment context, when the clinician determines the adolescent is at serious suicide risk, the clinician will probably want to hospitalize the patient. In most jurisdictions, the consent of a parent is sufficient for hospitalizing a minor, even over the minor's objections. State law varies as to the age at which an adolescent may object, the procedures available to an objecting minor, and whether certain youths, such as "mature minors" are able to give consent as though they were adults. If the parents do not consent to hospitalization or are unavailable, then involuntary hospitalization is available, provided the youth meets the state's civil commitment criteria. In treating a child or adolescent depressed patient, one dilemma that can arise is the extent to which the adolescent's confidentiality should be broken and the parents informed of the patient's status. It is useful at the outset of treatment to discuss with the minor patient the conditions under which the therapist will communicate information to the parents. When the clinician feels the need to discuss his or her patient's condition, for example, if a youth becomes more depressed and the therapist wishes to advise the parents to remove firearms from the home, it is preferable, when possible, to raise the need to talk to the adolescent's parents with the adolescent and obtain his or her assent. If the adolescent objects, but the therapist has significant concerns about the youth's safety, the therapist generally may discuss these issues with the parents over the adolescent's objections. This is allowable because in most cases the parents legally speak for the child and control access to information about treatment. In rare instances, such as when the minor is an emancipated minor or has "mature minor" status in a state that recognizes such a status, such a breach may not be possible, and the clinician then has fewer options. If the opportunity to involve the adolescent's support system is limited, the threshold for hospitalization is decreased.

Forensic psychiatrists are sometimes involved in determining the manner of death—whether the death was an unintended suicide, an accident such as unintended autoerotic asphyxiation (Sheehan and Garfinkel 1988), or suicide. The techniques employed in such analyses are similar to those utilized for adults.

A completed suicide by a patient in treatment may give rise to a malpractice action against the treating psychiatrist. When an outpatient commits suicide, a central question is likely to be whether the suicide was reasonably foreseeable, under the theory that if so, there was a duty to protect the patient, generally by hospitalizing him or her. The question of whether the suicide was foreseeable turns on the adequacy and documentation of the suicide risk assessment. Other issues that may come into play include whether appropriate informed consent was obtained for certain components of the treatment, whether the parents were sufficiently informed and involved in managing the patient, and whether the psychiatrist made available the means for suicide, as when an adolescent overdoses on antidepressant medication (much less common now with reduced use of tricyclic antidepressants), or any other defects that rendered the care below the standard of practice.

In 2004, the Food and Drug Administration (FDA) mandated a black box warning for the entire class of serotonin reuptake inhibitors (SSRIs) for youth based on a concern that SSRIs increase the risk of suicide in young people. Data analyses (Hammad 2004; Hammad et al. 2006) showed a doubling of reported suicidal thinking and behavior in youth receiving an SSRI from 2% for those on placebo to 4% for those on an SSRI, although there were no completed suicides in the sample. In 2007 the FDA revised the black box warning, limiting it to patients under 25 years of age and requiring appropriate monitoring, rather than a specific schedule implied in the previous black box warning (FDA 2007). The extent to which SSRIs cause suicide in youth remains controversial, in part because the data relied on for the black box warning included no completed suicides, that depression comes with a heightened risk of suicide so it is difficult in an individual case to determine whether the suicide resulted from the SSRI or from the underlying depression, and the data suggest the benefits of antidepressants in depressed youth outweigh the possible

risks (Bridge et al. 2007). Nevertheless, the existence of the black box warning means a clinician who prescribes SSRIs to youth is well advised to inform parents of the potential for increased suicidal thinking, especially in the 2 months following a new prescription or increase in dose, and to carefully monitor side effects of the medication. In the event of a malpractice case involving suicide while a youth was taking an SSRI, the informed consent process and monitoring of reactions to the drug will be carefully scrutinized.

In malpractice litigation involving an adult who committed suicide, the degree to which the adult was responsible for his or her own acts, and thus a contributor to the outcome, is often important. When a minor commits suicide, the presumption that minors are not as competent as adults often reduces the responsibility of the minor for his or her actions. As is typical in malpractice cases, the psychiatrist's notes in the chart will be carefully reviewed. When assessing a suicidal youth who is going to be treated as an outpatient, it is therefore very important from a risk management perspective to document carefully the assessment process, noting which risk factors and protective factors were assessed. The assessment process is an ongoing one, and documentation of the continuing assessment of risk is useful. In those cases in which the patient is not hospitalized, it is useful to detail the clinician's reasoning about how the risk factors were weighed in devising the treatment plan. The most difficult patients from a risk management perspective are those who are at chronic risk for suicide, for whom long-term hospitalization is not a reasonable option, but where the clinician is aware there is significant risk that at some point an attempt may miscarry and result in a lethal outcome. In cases in which the clinician believes his or her treatment plan carries significant, but justified, risk, one of the best risk management strategies is "when in doubt, shout" (Rappeport 1984)—have another clinician evaluate the patient and document his or her findings. In the event of an unexpected adverse outcome, the test will be whether the psychiatrist acted reasonably, and having a second reasonable clinician evaluate the patient can strongly counteract the retrospective analysis of a plaintiff's expert.

In a malpractice case following an adolescent committing suicide on an inpatient psychiatric unit, the two most common issues are completeness of the assessment of the patient's suicidality by the doctor and hospital staff, and the adequacy of the measures to protect the patient. Again, the quality of the continuing assessments and the extent to which they are documented are very important. One common issue is whether the attending psychiatrist was aware of clinical findings by the staff. Managed care has increased the threshold of severity necessary to justify inpatient hospitalization, and a high percentage of inpatients are hospitalized because of concerns about their suicidality. Therefore, the presence of some risk factors is quite common among inpatients. Once suicidal risk is noted, a central issue will be the level of monitoring of the patient, and whether decreasing the level of monitoring was justified.

Matters of self-destructive and suicidal behavior are likely to heighten the anxiety of the patient's relatives, opening the door to questioning and scrutinizing the psychiatrist's treatment. One risk is that the psychiatrist's own reaction to a patient's suicidality will lead to neglect of basic good practice (Simon 2000). Psychiatrists need not be intimidated by the complexities and uncertainties of dealing with suicidality. It is helpful to keep in mind that courts, peer reviewers, and managed care agencies ordinarily accept clinical decisions that are in keeping with a community's general standard of care, based on a rational consideration of the documented facts, and made in the service of the patient's welfare and well-being.

HOMICIDE

Epidemiology

For most of the past 20 years, homicide was the second leading cause of death for adolescents after automobile accidents (National Center for Health Statistics 2014). However, youth homicide rates have been dropping, and youth suicide rates increasing, so that in 2013, the suicide rate for all teenagers was slightly higher (CDC 2015). Querying the CDC's public WISQARS database reveals that in 2013, the overall rate of homicide for 15- to 19-year-olds was 6.74 per 100,000 (CDC 2015). Homicide from ages 5–14 was about one-tenth the rate for older adolescents. The 2013 homicide rate for children under age 5 was 3.33 per 100,000, practically all due to child abuse. For adolescents, rates for males are much higher than rates for females, and, for African American males 15–19 years old, in 2012 homicide was the leading cause of death, at a rate approximately quadruple that of motor vehicle accidents, and almost 10 times the rate for white adolescents (CDC 2014). Death rates from homicide for 15- to 19-year-olds had been fairly flat at about 10–12 per 100,000 from 1976 until 1987 when, within the next 4 years, the homicide rate doubled reaching a peak of over 20 per 100,000 in 1993. The rate then declined by about two-thirds, back to the rates of the 1980s (see Figure 43.1). The cause of the decline remains controversial.

A similar pattern is seen in the Federal Bureau of Investigation (FBI) statistics pertaining to juvenile homicide offenders. In 2012, juveniles were determined to have committed approximately 725 of the 11,521 murders in the United States where the offender's age was known (National Center for Juvenile Justice 2015). This represents a decrease of about 74% from the peak in 1994. The vast majority (91%) of the known juvenile homicide offenders were male, and more than 60% were African American. While African Americans are involved in juvenile homicides more frequently than whites, most of these differences wash out if the comparisons are controlled for the effects of socioeconomic status (Griffith and Bell 1989; Ellis et al. 2009).

The 1980s increase in youth homicide was strongly associated with an increase in firearm use among youth (Snyder and Sickmund 1999). Rates of intrafamilial

homicide and homicide with other weapons have stayed flat since the early 1980s. Blumstein and Cork (1996) hypothesized the increase followed a rapid increase of involvement of adolescents in the drug trade which led to increased gun carrying by youths. Why the rates subsequently declined, however, remains unclear (Blumstein and Wallman 2006). What is clear is that these changes in homicide rates mirrored a similar pattern of changes in rates of violent crime in the adult population, although the magnitude of increase was far greater among juveniles, and, interestingly, in youth suicide rates.

In previous years, acquaintances of the juvenile were more likely to be killed than strangers, but FBI statistics from 2012 involving juvenile offenders also reveal that murder victims were about equally likely to be acquaintances of the juvenile as strangers, and approximately 9% of victims were family members. Girls made up only 7% of the known juvenile homicide offenders, and girls were more likely than boys to use a knife or means other than a firearm than were boys, although firearms were the most common weapon used by both sexes (National Center for Juvenile Justice 2015).

Types of juvenile homicide

Homicide is a heterogeneous phenomenon among adolescents: the shooter who has been "dissed" outside a club, the adolescent girl who kills her stepfather because he has been sexually abusing her, and the psychotic adolescent who opens fire on his classmates at school represent very different pictures in terms of offenders, motivations, and victims. Studies of juvenile murderers have tended to be either interview studies of a convenience sample or analyses of FBI crime statistics. It is difficult to blend together these two different levels of analysis. There is a considerable literature on juvenile violence and its development, and homicide may present as the peak in severity of a violent career. Unlike suicide, it does not appear that juvenile homicide is primarily caused by mental health problems—although most offenders have psychiatric disorders—and many juvenile killers had not received psychiatric attention prior to offending. Findings over the past 14 years suggest it is useful to subdivide the conflict group into street confrontation, intrafamilial, and other, and to consider school shootings with multiple victims as a rare, but separate group. In addition, there are even less common subgroups, such as sexual homicide (Myers 1994), which have their own distinct characteristics.

Street homicides

Street violence is the most common form of juvenile homicide. Crime statistics often do not distinguish between street homicides occurring during the commission of another felony and street homicides arising out of conflict between youths. Gun carrying among adolescents is a major risk factor for homicide, as confrontations quickly escalate in lethality when one of the participants is armed. In many instances, the distinction between aggravated assault and homicide turns more on chance factors affecting the path of the bullet than on the intent of the shooter. When adolescents are asked about their reasons for carrying guns, keeping oneself safe is by far the most commonly cited reason (Ash et al. 1996). Although some adolescents report they derive an enhanced sense of power or self-respect from carrying a gun, few claim they carry a gun for the purpose of committing a crime. Most gun carrying by adolescents appears to be reactive in nature and is done because they fear harm on the street. Youths, particularly in minority groups, do face a much higher risk of victimization than the population at large. According to data from the CDC, in 2012, 17-year-old African American males were murdered at a rate more than eight times higher than their white peers and more than four times higher than the national average for all ages (CDC 2014). Adolescents who feel unsafe—especially those who live in inner-city neighborhoods where there is an "ecology of danger"—are more likely to arm themselves for protection, although the effectiveness of this strategy is debatable; handguns increase the likelihood of a violent confrontation. Whether fatal or nonfatal, street shootings heighten the overall level of fear in a community that, in turn, leads to rising levels of fear that encourage even more gun carrying (Blumstein and Cork 1996).

In those cities where gangs are prevalent, gang violence accounts for a substantial portion of youth homicides. Although there are difficulties in measuring levels of gang activity and whether a homicide is gang related, the CDC estimates that in Los Angeles, which has a high rate of gang activity, gangs are responsible for about three out of four youth homicides of 15- to 19-year-olds (CDC 2012).

There are three key points in the chain of events that precede almost every street shooting: first, the decision to acquire a handgun; second, the decision to carry it; and finally, the decision to use it. These are also the three key points for intervention. Most adolescents who become involved with guns acquire their first firearm in early adolescence (Ash et al. 1996; Brener et al. 1999). The majority receive their first gun from someone else, whether from a parent giving a child his first hunting rifle as a Christmas gift, or a teenager giving his best friend an illegally acquired handgun for protection. By middle to later adolescence, when delinquent boys are more likely to be arrested, they have begun to actively obtain handguns from a variety of sources, including buying from a drug dealer or an adult "straw purchaser," borrowing from a friend or acquaintance, or theft.

In an altercation between two inner-city youths, at least one of whom is armed, issues of respect and toughness—"being the man"—are very important, and perceived attacks on identity can rapidly escalate to lethal violence. In an analysis of transactions leading to inner-city street shootings, Fagan and Wilkinson (1998) emphasize the importance of a drug and alcohol context. Drug use worsens judgment, and the drug trade itself provides fertile ground for disputes over territory and payment. Fagan and Wilkinson emphasize the need to maintain hierarchy and respect in ways that feed

into maintaining a violent identity. The threat of gun violence introduces new complexities for development of social identity, resulting in the paradox that creating a "safe" social identity may require the use of extreme forms of violence.

In Myers et al.'s (1995) series of juvenile murderers who were seen for mental health evaluation, those juveniles who committed homicide during the course of another crime were found to have very high (>95%) rates of family dysfunction, disruptive behavior disorders, previous violence toward others and prior arrests, and high (>70%) rates of school failure, family violence, and learning disabilities. Benedek and Cornell (1989) found consistent findings but generally lower rates of disorder. In both groups, fewer than 25% had received prior mental health treatment. Fendrich et al. (1995) found about one-third of juvenile murderers were using substances, primarily alcohol, at the time of the offense, a rate that was lower than all but the oldest group of adult offenders.

Intrafamilial homicide

Rates of killing a family member have been holding steady or decreasing since 1993, and in 2012 accounted for 9% of juvenile homicides (National Center for Juvenile Justice 2015). Parricide, killing the father, is the most common form (Heide and Petee 2007), generally found in the context of abuse and, when it occurs, is most often committed by older and depressed adolescents (Dutton and Yamini 1995). In many cases, unlike with street homicides, the adolescent does not exhibit a prior history of delinquency. The criminal defense of these youth often emphasizes the abuse victim status of the killer as a mitigating circumstance of the killing.

Psychotic motive

While psychotic motive overlaps the other categories, it is frequently dealt with separately, because it has different implications with regard to sentencing and treatment. In criminal justice statistics, psychotic motive is not broken out as a separate category, so overall rates are unclear, but in reports of cases referred to mental health professionals, psychosis is uncommon, accounting for less than 7% of cases (Benedek and Cornell 1989; Meloy et al. 2001). Myers et al. (1995) found no psychotic youth in their sample, although they found a history of psychotic symptoms in 71% of subjects. Psychotic juvenile defendants may be found not criminally responsible and referred for treatment of their psychosis.

School mass shootings

Statistically, schools are a safe place to be. About 1.3% of all youth homicides occur at school, a rate that has remained fairly stable over the past 20 years (Planty and Truman 2013). The first mass killing of students by a student in a U.S. K–12 school occurred in 1996 when a 14-year-old boy in the Frontier Middle School shot and killed a teacher and two students and wounded another in his algebra class. In the following 4 years, there were six additional incidents of mass killings by students in K–12 schools, the most deadly of which was the mass shooting at Columbine High School in Colorado, during which 12 students and 1 teacher were killed, 24 people were wounded, and the two student shooters committed suicide (for descriptions, see Verlinden et al. 2000; Wikipedia 2015). These shootings generated enormous amounts of media coverage and grave concerns about school safety. The clustering of the shootings in such a brief period strongly suggests a contagion effect. Such shootings, while fortunately very rare, nevertheless create a climate of fear in schools which has an impact on students' emotional well-being, their readiness to learn, and the hiring and retention of teaching staff.

Studies of school shootings (Verlinden et al. 2000; Reddy et al. 2001), the influential FBI report in 1999 (O'Toole 1999), and the reports of the U.S. Secret Service and the Department of Education's Safe School Initiative in 2000 and 2002 (Fein et al. 2002; Vossekuil et al. 2002), were consistent in finding that there was *no* profile of a school shooter that would prospectively identify the perpetrators. Except for the fact that all were male, the perpetrators were quite varied: few attackers had no close friends—only about a third were characterized as loners—and the majority had never been in disciplinary trouble at school or had a history of violence. Many attackers had felt bullied or persecuted at school. Of the 37 school shootings investigated by the Safe Schools Initiative, only one-third of the attackers had ever received a mental health evaluation, and only seven (17%) had ever been diagnosed with a mental health or behavioral disorder (Vossekuil et al. 2002). The most significant finding was that in almost all cases, the perpetrator had mentioned his plan to at least one peer, but there was a failure of peers to take the threats seriously and report the threats to school authorities. This finding led to an emphasis on encouraging students and staff to report all threats, even threats made as jokes, to school authorities, who would then institute a threat investigation.

Building on earlier work of the U.S. Secret Service in evaluating threats to the President (Fein and Vossekuil 1999), threat investigation of people with or without mental illness has moved away from profiling the subject to evaluating the pathways that lead to violent action (Borum et al. 1999). Put another way, threat assessment looks less at characteristics of the subject (such as stated intent, psychopathology, and access to weapons) and more at recent behavior that suggests the subject is moving on a path toward violence. This path typically begins with ideation, such as interest in mass killing or assassination, progresses through fantasies of killing, moves to a discreet planning stage (scouting out locations, selecting targets) and means acquisition (obtaining weapons), and culminates in offensive action. Because an individual in a psychiatric interview may deny many of these recent behaviors, a comprehensive evaluation involves obtaining collateral information (e.g., from peers and perhaps computer records, such as Internet browsing history).

A number of protocols have been developed to assist schools in implementing threat assessment protocols in the school environment (Fein et al. 2002; Cornell and Sheras 2006). These protocols emphasize developing multidisciplinary teams, and they detail the process of threat assessments. These multidisciplinary teams typically include school administrators, law enforcement personnel, and mental health professionals. Assessments begin with a triage process that considers the seriousness of the threat. Not all threats are serious. One study of the Virginia Student Threat Assessment program (Cornell et al. 2004) found that 70% of threats were transient and could be resolved quickly. The remaining substantive threats required more extensive evaluation and development of a safety plan to ensure the safety of the school and meet the educational needs of the threatening student.

The approach of encouraging students and staff to report threats, and then to actively investigate such threats, appears to have been effective in significantly reducing mass shootings in K–12 schools. In the 15 years since the Columbine shootings, there have been only four instances of mass shootings by students at K–12 schools that resulted in two or more deaths, not including the suicide of the shooter. Although no national statistics regarding the number of attacks thwarted by threat investigations are available, numerous anecdotes and news reports of interventions that have prevented planned attacks have been reported.

Legal issues

When a therapist is aware that a patient is dangerous to others because of mental illness, he or she will most commonly hospitalize the patient, involuntarily if necessary. In many states, therapists now have a *Tarasoff*-type duty to protect third parties, though the precise nature of the duty varies from state to state. The laws with respect to civil commitment and protection of third parties embody the same principles for adolescents as for adults.

Many states responded to the wave of juvenile violence in the early 1990s by passing laws that make it easier to try an adolescent in adult court, either by enacting discretionary waivers, which give the prosecutor discretion as to whether to waive the adolescent defendant, or mandatory waivers, laws that require that adolescents over a certain age and charged with certain crimes be tried in adult court. Homicide, being the most serious offense, heads the list of crimes for which waivers are invoked. Therefore, most youth arrested for homicide are tried as adults. In adult court, issues of competency to stand trial and insanity defense can be considered. Although many middle-to-late adolescents make decisions similar to adults, the determination of a younger adolescents' competency may turn on complex developmental issues, and so the techniques for evaluation are somewhat different than with adults (see, e.g., Mossman et al. 2007; Grisso 2013). The two strongest predictors of an adolescent's competency to stand trial are age and IQ (Ash 2003). Adolescents whose competency is seriously diminished will often be remanded to juvenile court. In addition to competency to stand trial, competency to confess may also be at issue. If a juvenile defendant is found incompetent to stand trial, the question of how his or her competence is to be "restored," when what may be needed is time for him or her to cognitively mature, poses knotty problems for interim disposition.

If the juvenile is not automatically waived to adult court on a murder charge, the issue of the judicial waiver to adult court needs to be considered. In many states, competency to stand trial is now required for a youth to be tried in juvenile court as well.

Insanity defenses for juveniles are relatively rare, largely because the incidence of psychosis is considerably less in minors than in adults. Only a small minority of states allow the insanity defense in juvenile court (Pollock 2001).

Psychiatric evaluations are sometimes sought to aid the court in sentencing adolescents. In the past decade, the U.S. Supreme Court has limited the punishments that can be given to adolescents (those under 18). In *Roper v. Simmons* (2005) the Court held that executing a person for a crime committed while an adolescent is cruel and unusual punishment and therefore unconstitutional. In *Graham v. Florida* (2010), the Court held that life without parole (LWOP) for crimes less than murder was unconstitutional, and in *Miller v. Alabama* (2012), the Court held that mandatory LWOP for adolescents convicted of murder was unconstitutional, although states could still allow a judge to hand down an LWOP sentence for murder following a hearing on its appropriateness in a specific case. Mental health testimony in sentencing hearings for murder convictions frequently focuses on issues of adolescent culpability (see Chapter 48).

Prevention

Psychiatry is fairly weak at predicting violence toward others, and most of the mental health research done has focused on adults, particularly psychiatric inpatients. It is unclear the extent to which the principles developed for adults generalize to adolescents, particularly because psychosis and substance abuse play a much smaller role in adolescent crime. If a patient expresses homicidal intent, a clinician has good grounds to intervene, but in the absence of expressed intent, risk factors such as a prior history of violence are so nonspecific as to be of little help in most individual cases. Homicide in adolescents frequently occurs impulsively, without prior threats or expressed ideation, which adds to difficulties in prediction. The widely fluctuating rates of juvenile homicide over the past decade and the difficulty in identifying prospective murderers suggest that interventions at the community level are likely to have the most effect in reducing mortality. Juvenile homicide is the tip of the iceberg of youth violence, and reducing youth violence generally is likely to reduce the juvenile homicide rate.

Given that most homicides are firearm related, reducing carrying of firearms appears among one promising strategy targeting juvenile homicide. While a sense of need for protection is the leading factor motivating gun carrying, fear of being caught with a gun is the strongest

deterrent (Ash et al. 1996; Freed et al. 2001). The federal Youth Handgun Safety Act (1996) makes it illegal for juveniles to carry a handgun. Some pilot strategies that appear useful in deterring adolescents from carrying guns include enhanced prosecution of gun offenders (Seattle, Washington), directed police patrols aimed at deterring illegal gun carrying (Kansas City, Missouri), parental consent for police to search a juvenile's room and confiscate firearms found there (St. Louis, Missouri), and holding a gang responsible for the actions of individual members (Boston, Massachusetts). There is ample, albeit indirect, evidence that if an area is perceived as safe and well policed, young people are less apt to bring guns there. Schools are one clear example of this. A recent report from the U.S. Departments of Justice and Education finds that rates of gun carrying on school property have been falling and that youths feel safer in school than previously (Robers et al. 2014). It is unclear whether teens decline to carry guns to school because they feel they are unlikely to encounter an armed rival or because they fear detection by vigilant teachers, classmates, or school security technology and the penalties of "zero tolerance" policies. What is clear, however, is that the collective impact of these interventions has been positive. Schools are also promising sites for interventions with adolescents to build a sense of community and promote and teach nonviolent coping skills.

At a community level, a "rebuilding the village" approach involves collaborations between citizens, businesses, and government to promote a safer, healthier environment (Bell et al. 2001). A wide variety of techniques for promoting community health are available (see, e.g., Asset-Based Community Development Institute 2015).

SUMMARY

Adolescent violence, directed against self or others, exacts an enormous toll on its victims, their families, and society. Forensic psychiatrists are frequently consulted to assess cases involving youth, primarily adolescents, who are either thought to be at risk for killing themselves or others, or have already done so. Because of the high stakes involved, such cases generate great anxiety and concern for evaluators, patients, and families. Although a good deal of group data about these juveniles has been developed, our ability to predict accurately which individuals will carry out such violence remains severely limited. Clinical approaches for assessment and intervention have been developed. Psychiatric intervention has no doubt benefitted many at-risk patients, but rigorous research has so far not demonstrated a consequent significant decrease in death rates. This may in part reflect that many youth who kill themselves or others never see a mental health professional. Family and community interventions may have the most effect in reducing mortality.

The child as a witness

SUZANNE M. DUPÉE

INTRODUCTION

Children can be called as witnesses in various different legal proceedings: as a perpetrator in juvenile cases, as an eyewitness or victim in a criminal case, as a victim in a child abuse case against the child's parents or other caregiver, in a custody battle between feuding and divorcing parents, or as a witness or victim in a civil matter. Despite the setting or context, the courtroom or other legal venues are usually out of the normal realm of children's environment. The courtroom is not a familiar playground for children, and litigation is by definition a contentious process. Child witnesses are thrust into highly contentious legal dilemmas, often with high stakes at issue, e.g., capital cases, child abuse cases, criminal cases, or custody cases. Depending on the age of the child, the child often has little to no understanding of court proceedings. The child's voice might be important, such as voicing custodial preferences in child custody disputes, but the child has little to no knowledge, limited rights, and often little protection in highly adversarial settings.

Before testifying as a witness, it is likely that a child has been prepped in some way—either by the child's own parent, law enforcement, a social worker from child protective services, a lawyer representing the child, or the child's parents. Sometimes the child is on the witness stand with little preparation or briefing. Often the child's testimony holds weight that can influence the outcome of the litigation. Sometimes the child's testimony holds little value. Sometimes the absence of the child's testimony can lead to the inability to prosecute child sexual molesters or sway a family judge to make decisions that are not in their own best interests. Depending on the type of litigation, children are likely to have no legal representation. Depending on the nature of the preparation, children might be adversely influenced or suggestible in their testimony that in turn might affect the outcome of the case. The legal system is a daunting place for children.

An intricate understanding of child development is optimal to obtain pertinent and accurate information from children and for justice to be served for all participants. Child psychiatrists and forensic psychiatrists can play an important role in the legal system in many different arenas. They can educate attorneys, judicial officers, and law enforcement about child development and interviewing children. They can consult with attorneys about child-related cases. They can be called upon to opine about competency to stand trial in juvenile delinquency cases.

History of child witnesses

> Children are the most dangerous of all witnesses.
>
> *A. Baginsky*

EARLY ENGLISH AND AMERICAN HISTORY

Children have been involved in legal cases for thousands of years dating back to Cain and Abel. In the seventeenth century judges were skeptical of child witnesses in sexual molestation trials, and they reduced sentences for convictions of child sexual perpetrators (Steenburg 2005). The 1692 Salem witch trials are the most famous and most referenced in regard to leading questions. Hundreds of 5- to 12-year-old children testified to observing bizarre witchcraft and wizardry. Much has evolved since the Salem witch hunt trials.

In England in 1779 the decision in *Rex v. Brasier* held that there is no age below which children are automatically disqualified from testifying (*Rex v. Brasier* 1779). In Jewish history, child witnesses had to be "of full age"—more than 13 years old (Whipple 1911). In the Antebellum Period before the American Civil War, the notion that children needed sheltering from the responsibilities and realties of adult life emerged in law and policy (Tanenhaus 2007). The "best interests" doctrine emerged as early as the mid-nineteenth century (Grossberg 1996). The twentieth century saw an explosion of research about child and adolescent development that has paved the path for more understanding about present-day child witnesses.

Landmark cases and laws pertaining to child witnesses

The evolution of cases involving child witnesses dates back centuries. After an outcry over failed prosecution in sexual abuse cases in the 1980s, hearsay exceptions for child witnesses is widely employed (Raskin 1989). Federal Rules of Evidence (Fed. R. Evid. 1984) established guidelines regarding child witness testimony and hearsay. Child witnesses are not excluded as witnesses irrespective of their age. Federal courts and most states allow hearsay evidence of children. Federal Rules of Evidence 801 (Fed. R. Evid. 801) defines hearsay as "a statement, other than one made by a declarant while testifying at the current trial or hearing offered in evidence to prove the truth of the matter asserted in the statement." Federal Rules of Evidence 803 lists 23 hearsay exceptions. Children's statements made to nonforensic professionals might be deemed hearsay and therefore are inadmissible (McGough 1996) but may qualify for the hearsay exception through Federal Rules of Evidence 803(4) (Fed. R. Evid. 803), which provides that the following statements are admissible as hearsay if they are made for purposes of medical diagnosis or treatment and describing medical history, pertinent to diagnosis or treatment. Another exception is Federal Rules of Evidence 803(2) (Fed. R. Evid. 803), which relates to "the excited utterance"—"a statement relating to a startling event or condition, made while the declarant was under the stress of excitement that it caused." The U.S. Supreme Court case *Ohio v. Clark* (2015) further extended issues regarding hearsay by protecting mandated reporters' initial questioning of possible child abuse victims.

Over the past two decades various evidentiary and procedural innovations have been introduced to reduce the barriers associated with children as participants in legal proceedings. Victims of Child Abuse Act of 1990 extended special accommodations to children, such as the presence of a support person during the child's testimony and a closed courtroom to the general public (Whitcomb et al. 1991). These accommodations include hearsay exceptions, videotaped testimony, and closed-circuit television (CCTV) (McAuliff and Kovera 2002; McAuliff et al. 2013).

Most states have taken steps to institute closed-circuit testimony to codify standards articulated in *Maryland v. Craig* (1990) to reduce the trauma to child abuse victims. CCTV testimony is more common in other countries such as Australia (Cashmore and De Haas 1992), and Britain (McAuliff and Kovera 2002) than in the United States (McAuliff et al. 2013).

Distinction between clinical or treating and forensic evaluations is a critical element in the legal process and attempts to minimize hearsay exceptions, because expert opinions may rely on hearsay (Fed. R. Evid. 703). Appeals of criminal convictions regarding admissibility of hearsay are common. Table 44.1 summarizes landmark English and American cases related to child witness testimony.

Children in court

Many court systems involve children directly or indirectly. Common settings for child witnesses are

1. Family court
2. Dependency or child protection courts
3. Civil court
4. Juvenile delinquency courts
5. Adult criminal courts

The first three settings are civil arenas where the child is often the primary subject of the litigation, whereas in juvenile court children are defendants or adjudicates, and in adult criminal court children are witnesses whose testimony might be the critical deciding factor influencing the outcome of the criminal trial. In child sexual abuse cases, multiple court systems are often involved: criminal, family, and dependency. The stakes, rules of evidence, and burden of proof are highest in criminal cases. Often the outcome of one case dictates the direction and outcome of another if cases span several systems.

Children are not experienced legal system participants. The concern that children will be traumatized or revictimized has been paramount for many decades. Children are often asked details about personal and often incriminating information about an important person in their lives (Tedesco and Schnell 1987). Berliner and Conte (1995) found that children reported primarily favorable experiences following disclosure of sexual abuse with increased distress related to more contacts with intervention professionals. Subsequently, a national movement to streamline the process of coordinated interviews and children advocacy centers was spawned (Henry 1997).

FAMILY COURT

In family court, the best interest of the child is the prevailing standard across the United States in custody battles. Many family court judges decide on custody of children in divorce without having the child testify. Children can find themselves involved in family court proceedings directly or indirectly as the focus of child custody disputes or as potential witnesses in their parents' legal cases of divorce or separation. If a custody evaluation is ordered or stipulated by the parties, children are always interviewed by a mental health professional or in some states by a guardian ad litem to determine the best interests of the child. The length of time spent on interviewing children ranged from 1.6 to 3.6 hours (Ackerman and Pritzl 2011). Evaluators are ethically bound not to provide custody recommendations without observing children with their parent or guardian (American Academy of Child and Adolescent Psychiatry 1997; Association of Family and Conciliation Courts 2006; American Psychological Association 2009; Martindale and Task Force for Model Standards of Practice for Child Custody Evaluation 2006).

Table 44.1 Landmark English and American cases

Case name	Description	Ruling	Significance
Rex v. Brasier (1779)	England	There is no age below which children are automatically disqualified from testifying.	Age of children to testify was addressed.
Wheeler v. US (1895)	Competency of children in a murder case involving a 5-year-old witness testifying against his father	There is no precise age that determines competency. Admissibility depends upon their ability to understand telling truth versus lies.	Age is not an exclusive witness determinant. Assessment of ability to tell the truth is critical.
Kentucky v. Stincer (1987)	Child sexual abuse case of 8-, 7-, and 5-year-olds. The defendant did not attend the competency hearing and appealed under the Confrontation Clause of the Sixth Amendment and Due Process under the Fourteenth Amendment.	The defendant's rights were not violated by not attending the competency hearing. The defendant's presence would not contribute to the fairness of the proceedings because neither girl was honest about substantive testimony.	Ratified procedures for evaluating competency of child witnesses.
Coy v. Iowa (1988)	Coy charged with sexual assault of two 13-year-old girls who were camping in the backyard of his neighbor. Neither girl could describe his face when they were assaulted. Trial court approved use of a large screen to be placed between the accused and witnesses. Defendant objected to use of screen based on Sixth Amendment Right to Confrontation and Fourteenth Amendment Right to Due Process.	Trial court rejected constitutional claims but instructed jury to draw no inference of guilt from screen. Defendant convicted of two counts of lascivious acts with a child(ren). U.S. Supreme Court held that the defendant's Sixth Amendment rights were violated.	Criminal defendants have the right to confront their witnesses to ensure fairness and integrity of the fact-finding process and make it more difficult for the witness to lie. The child's protection against facing the defendant was trumped by the Confrontation Clause of the Sixth Amendment.
Globe Newspaper v. Superior Court (1982)	Trial involved male accused of raping three minors. MA statue excluded members of the press and public from sexual offense and testimony of victims less than 18 years old. Globe challenged statue based on First Amendment violation.	U.S. Supreme Court held that the Globe Newspaper's constitutional right to face-to-face confrontation was violated. U.S. Supreme Court reversed and remanded the lower court's findings.	Exclusion of the press and public from child sexual offences cases violates the First Amendment apart from a caveat that child witnesses needed special protection.
Commonwealth v. Corbett (1989)	Defendant was charged with indecent assault and battery on a child under 14. Alleged 4-year-old victim was due to testify as the only percipient witness.	Judge found the child incompetent to testify.	Difficulties in assessing children's competency in criminal cases.
Idaho v. Wright (1990)	Female accused was charged with lewd conduct with minor, her 5-and-a-half and 2-and-a-half daughters.	Holdings of U.S. Supreme Court upheld that of the State Supreme Court and found that the pediatrician's interview techniques were unreliable and conducted in a suggestive manner.	Interviews conducted of children without video- or audiotaping and with leading questions lack trustworthiness and are not admissible.

(*Continued*)

Table 44.1 (*Continued*) Landmark English and American cases

Case name	Description	Ruling	Significance
Maryland v. Craig (1990)	Kindergarten owner and operator charged with first- and second-degree sexual offense of perverted sexual practice and assault and battery against a 6-year-old girl. State requested testimony via one-way closed-circuit television. Court found that courtroom testimony of the children would cause them serious emotional distress and they would stop talking and withdraw. Defendant was convicted.	The State has an interest in protecting child witness from the trauma of testifying in a child abuse case if sufficiently important to justify the use of a special procedure to avoid confrontation of the defendant. The distress must be more than *de minimis*, i.e., more than mere nervousness or reluctance. Decided on a case-by-case basis.	Child witnesses' protection to avoid confrontation of the defendant due to severe distress.
Tome v. U.S. (1995)	Divorced father charged with sexually abusing his 4-year-old daughter when she was in his custody.	Supreme Court reversed the Court of Appeals decision and held that the conditions of admissibility of some out-of-court statements where not established.	Addressed the question of whether out-of-court consistent statements made after be alleged fabrication or after alleged improper influence or motive are admissible under Federal Rules of Evidence.
Ohio v. Clark (2014)	Allegations of physical abuse of young children physically abused by their mother's boyfriend. A preschool teacher inquired about the injuries and made a child abuse report naming Clark as the perpetrator. Can a reporter become an agent for law enforcement for purposes of the Confrontation Clause and whether a child's out-of-court statements to a teacher in response to the teacher's concerns about potential child abuse qualify as "testimonial" statements subject to the Confrontation Clause?	Supreme court of Ohio reversed the lower court's conviction holding that the teacher was acting as a law enforcement agent when enquiring about the injuries. Out-of-court statements could only be admitted if the primary purpose of the teacher's questioning was to address ongoing emergency as opposed to establish past events.	Mandated reporters do not act as law enforcement agents. Out-of-court statements admitted if mandated reporter questions address immediate emergency.

Some children of divorcing parents receive therapy from mental health professionals, while the majority has no personal mental health support. Many courts appoint either a guardian ad litem or minor's attorney in complicated or high-conflict family law cases. In some jurisdictions children frequently testify in family law or criminal cases either as witnesses to domestic violence between their parents and/or to express their custodial preference.

In January 2012 California adopted Rule 5.250 allowing children to participate in family law matters on a case-by-case basis. If the child 14 years or older expresses an interest in addressing the court, the judicial officer must hear from that child unless the court makes a finding that addressing the court is not in the child's best interest and states the reasons on the record (California Rules of Court 2012). The judicial officer must consider whether the child is of sufficient age and capacity to reason to form an intelligent preference as to custody or visitation, to understand the nature of testimony. The court must determine if the child might be at risk of emotional harm or may benefit if he or she is permitted or denied the opportunity to address the court. Further the child must address issues relevant to decision making. Finally, the court must assess other factors related to the child addressing the court.

Interviews in child custody evaluations are by definition less formal, often more extensive, and follow a different format than child testimony in family court. Evaluators are trained to focus on building rapport with the child, not directly ask questions of preference (e.g., which parent do you want to live with) in order to illicit information helpful to make their recommendations to the court, whereas child witnesses are subject to formal testimony and cross-examination in an unfamiliar setting of the courtroom. Most courts close child witness testimony to the general public in family court hearings.

DEPENDENCY COURT

Children in dependency court cases are often extensively interviewed by forensic professionals: police, social workers, mental health professionals, child advocates, attorneys, and/or judges. Children in dependency court do not fare well on many indicators compared with the overall population and desire a voice in decision making (Bessell and Gal 2009).

Block et al. (2010) interviewed children in dependency court who attended their juvenile detention hearings. They found that lack of understanding and negative attitudes were common. They concluded that maltreated children may profit from greater understanding of dependency court. They also found that children often wish to have greater influence in dependency court decisions.

Runyan et al. (1988) implemented a structured psychiatric inventory of 75 sexual abuse victims at referral and 5 months later. They found that all children demonstrated a high degree of distress at the referral to Child Protective Services. They found that the anxiety in children who testified in juvenile and dependency courts improved 42% or 20 times on the Child Assessment Schedule Anxiety subscale. They concluded that testimony in juvenile court might be beneficial for the child, whereas they found that protracted criminal proceedings may have an adverse effect on the children's mental health.

In a subsequent multisite study by Whitcomb (1994) through the National Institute of Justice, they found that children showed distress at the initial interview but improvements on follow-up interviews. However, they found that repeated testimony and harsh cross-examination were found to be related to significant adverse effects.

CIVIL COURT

Children involved in civil proceedings are either witnesses or more commonly plaintiffs in civil tort actions. Legal civil cases involving children include personal injury, e.g., a motor vehicle accident or other accident, or a child sexual abuse case filed against a defendant. Children in civil cases are at the behest of their parents or guardians who have filed the action on their behalf. They are often subjected to depositions, evaluations by numerous retained experts on both sides, and testimony in court regarding the issue being litigated. Depositions can be stressful to children in different ways than testifying in open court, where they are often protected by the judge, with stricter protocols than in an attorney's office, often with many people and video cameras on. The exposure to the legal system often causes litigation stress and causes the child to relive the trauma expressly for litigation purposes.

JUVENILE DELINQUENCY COURT

Children and adolescents can also be involved in the legal system as delinquents. Teen or youth courts provide alternate early intervention dispute disposition for youths. They are staffed by youth volunteers who act in the roles of court personnel. This informal setting where a youth is judged by his or her peers might assist the delinquent in giving more informal testimony than adult court settings. Little research exists on the impact of children as witnesses in teen court.

ADULT CRIMINAL COURT

Quas et al. (2005) completed a long-term study of 174 of the original 218 child victims/witnesses involved in a short-term study 12 years prior. They found that being young at the outset of the legal case was associated with poorer later adjustment. Testifying repeatedly in cases involving severe abuse, and not testifying when the perpetrator received a light sentence, predicted poorer current mental health. When the perpetrator received a lenient sentence, more negative feelings about the legal system were felt by older children. Additionally, not having testified when the perpetrator received a light sentence predicted more negative attitudes. Greater distress predicted poorer adjustment. Older children spent more time on the witness stand (Whitcomb et al. 1991). Other forms of distress include facing and accusing the defendant (Goodman et al. 1992; Plotnikoff and Woolfson 2004).

Andrews and colleagues (2015) reviewed 120 transcripts of 6- to 12-year-old children testifying in sexual abuse trials. They found that neither prosecutors nor defense attorneys question children in developmentally appropriate ways and that children were more unresponsive to defense attorneys than to prosecutors.

Modern research on children's development and memory

Unlike most adults who are witnesses in forensic cases, children present a wide range of important factors to consider if they are called as witnesses. The child's stage of development with regard to the child's cognitive skills and memory is a critical factor to assess when the child is a witness. A 5-year-old child's ability to perceive, remember, organize, process, store, retrieve, and recall events will be vastly different from that of a 15-year-old and also different from children aged two or three.

COGNITIVE DEVELOPMENT

Children perceive the world differently than adults. A child's development is a sequential increase in the structural and/or functional complexity of a system (Yates 1996). According to Piaget's theory of cognitive development, memory constantly increases in complexity over a child's life.

Toddlers and very young children are egocentric, i.e., they are unable to perceive events and experiences from any

point of view other than their own. They use *transductive reasoning*—a faulty type of logic involving making inferences from one particular to another in an illogical manner. They lack the ability to understand cause and effect. Logical contradictions are not important or appreciated. This type of thinking can easily lead to incorrect conclusions and serious ramifications in the justice system (Powell 2013).

Preschoolers (3- to 6-year-olds) become increasingly more cognitively sophisticated, and their language allows them to express themselves verbally and in writing. At around 4 years old, children enter a substage of *decentration* where they become increasingly accommodated to reality, and their own perception and interests decenter and they become aware of their own capacities. They acquire better understanding of time and space—important elements in many forensic evaluations. By this age, children's thinking becomes more logical.

Elementary school-aged children develop the ability to consider different variables. They enter the phase of concrete operations. They can distinguish between fantasy and reality, apply logic to their concrete experiences without interference of their perceptions, and put their feelings more into context. They often operate under *assumptive realities*, assumptions based on limited facts, which they do not alter in the face of contradictory evidence (Elkind 1970). In forensic settings *assumptive realities* might be the difference between conviction and acquittal.

Six or seven years old is a critical turning point in terms of a child's thinking, corresponding with entering first grade. A 6-year-old can distinguish between real and imagined events. A 3-year-old cannot. When children enter the formal operational stage (11 years old to adulthood), they develop the ability to abstract and construct.

The concept of time is often a critical issue in many forensic cases, especially in criminal cases. The ability to make accurate chronological judgments improves gradually across development (Friedman 1977, 1986, 1991, 2000; Carni and French 1984). A toddler has a relative absence of the meaningful sense of time. When toddlers are asked time frames, dates, or other time-sensitive information as part of their interview or testimony, they are unlikely to be able to describe the sequence, length, or details of events that might be out of their daily routine. Preschoolers do not comprehend relational terms (before, after, if, so, because, or, and but) until several years later, even though they spontaneously and correctly use these terms (Carni and French 1984).

Language is an important aspect with children in forensic settings. Children are not credible if they cannot communicate effectively. They might be required to offer testimony on concepts that are developmentally beyond their developmental stage (Segovia and Crossman 2012). Evans and colleagues (2009) analyzed 46 child sexual abuse case transcripts and concluded that attorneys' language influenced the accuracy of a child's testimony. Complex questions asked by defense attorneys predicted convictions rather than acquittals.

Lawyers and judges are rarely experts or even educated in the area of child development and psychology. Their jargonistic language is confusing to many adults and a foreign language to children. Young children's articulation is often not mastered in preschool children, therefore leading them to be misunderstood when interviewed. Their vocabulary is limited, thereby limiting their ability to provide details and descriptions of important facets of a case.

Competency, honesty, and credibility are critical factors in any forensic evaluation. In the courtroom a witness can only testify if he or she is sworn in. Children's competency to understand the oath is essential for the legal process. Evans and Lyon (2012) conducted a study with 164 child witnesses in criminal child sexual abuses cases tried in Los Angeles County and 154 child witnesses in U.S. State and Federal Appellate cases. They found that judges almost never found children incompetent to testify, but children exhibited substantial variability in their performance based on question type, and the children's truth–lie competency is underestimated by courtroom questioning.

Cognitive development encompasses the process of moral development. Children learn to lie very early in their development; however, children under the age of 3 have difficulty carrying out more sophisticated deceit. To understand the concept of a lie, children must understand the concept of truth. A child's ability to lie is related to his or her specific stage of cognitive development. Additionally, social and motivational factors affect their honesty (Talwar and Crossman 2012). Bussey and Grimbeek (2000) studied children's knowledge about and evaluation of lies and truths and concluded that 4-year-olds have sufficient understanding of lying and truth-telling competence to participate effectively in the legal system.

Memory of events and information is a critical element in forensic cases. There is a plethora of research about memory development and suggestibility with regard to children as witnesses in forensic settings. Most commonly children in legal proceedings are asked and expected to describe events that occurred in the past—it could be the immediate past in cases where children are interviewed within hours or days of the event, or years later, e.g., when a criminal or civil case goes to trial.

Memory is a complicated flow of information through a system that stores, organizes, encodes, and retrieves. Information can be lost at any stage. Memory can be divided into procedural, episodic, and semantic memory storage. Procedural memory involves remembering how to accomplish learned tasks such as tying one's shoelaces. Episodic memory stores up autobiographical memory (recalling oneself in an event). Semantic memory stores knowledge representations or general knowledge (Williams et al. 2008). Information gathered in testimony relies on declarative memory or episodic memory. Until about 3 years of age, autobiographical memory rarely persists to allow recall and reporting of an experienced event (Fivush 1994, 1997). Humphries et al. (2012) found that children as young as 5 years old can still be accurate in identifying culprits from video lineups. However, age was also significantly associated with accuracy. Testimony mostly relies on declarative-type

memory or episodic memory, i.e., information linked to occurrences and, even more specifically, autobiographical memory. The development of autobiographical memory marks the emergence at which children can be expected to give testimony (Gordon et al. 2001).

SUGGESTIBILITY

Suggestibility is the ease of influence and persuasiveness to questions in a leading interview in which one accepts and changes his or her own judgments, opinions, or patterns of behavior (Drukteinis 2001).

A pivotal case of widespread suggestibility in young children was the California McMartin case in which over 350 preschoolers were interviewed with highly suggestive methods of questioning and led to false allegations of widespread child sexual abuse that were widely fanciful and bizarre, such as flying witches, secret tunnels under the school, orgies, children being flushed down toilets, and naked movie star games. The multimillion-dollar trial devastated the accused but ultimately led to reform of research of childhood sexual abuse. Not all children are suggestible though. Even in the McMartin case, some children were resistant to suggestive questioning.

Most of the research regarding suggestibility in children has focused on interview techniques. Principe et al. (2006) found that peer and family conversations were a common source of influence of child witness testimony. They studied how an erroneous rumor circulated among preschoolers can influence their memory. They found that naturally occurring conversations and interactions with classmates were as likely to report experiencing rumored events that they did not experience as were those who actually experienced it. Further, most of the reports of the rumored but nonexperienced events were in children's free recall, and were accompanied by high levels of fictitious elaboration. This finding is a powerful tool for attorneys in a wide range of cases including child custody, sexual abuse, and child neglect and physical abuse cases to discredit child witnesses.

FACTORS INFLUENCING CHILDREN'S MEMORY

Children's testimony is dependent on many variables including their age, exposure to trauma, traumatic reaction related to the event or events in question, time elapsed from the event to the testimony or interview, repeated interviews, prior knowledge, race and socioeconomic status, gender, interview aids, influence from authority figures, and interviewer bias.

Children as young as 3 or 4 years old can remember and report events with enough clarity and accuracy to assist triers of fact in rendering a verdict (Hershkowitz et al. 2012; Powell 2013). Three year-olds can provide information about experienced events; however, the ability to provide narrative responses to open-ended recall prompts only becomes reliable later in development. Even very young children can provide rich accounts of their experiences (Bahrick et al. 1998) that can endure for long periods of time (Schwartzmueller et al. 1996; Howard et al. 1997; Peterson 1999; Gordon et al. 2001).

When children have to testify about numerous events and not one single event, the accuracy of their recollection can be questionable depending on their age. Roberts et al. (2015) found that older children were more able than younger children to judge relative order of occurrences and that they remembered the first and last occurrences compared to the middle occurrences in older children, while younger children only remembered the first occurrence.

Older children are able to reconstruct a narrative in response to simpler prompts such as "what happened?" Several researchers studied the effect of free recall. Dent and Stephenson (1979) found that the free report produced highly accurate but incomplete recall. Further, Poole and Lindsay (2001), Goodman et al. (1994), and Greenhoot (2000) found that contrary to urban myth, children's spontaneous statements and free recall statements are not error free. Children's free-recall and spontaneous statements are generally more accurate than their responses to directed questions.

Our past experiences shape our perception of events. For children, their experiences in the world are exponentially limited compared to those of adults. Every day adds a new experience to their repertoire and therefore shapes their memory and subsequently their perceptions of the world. In legal proceedings the accuracy of children's memories is influenced by their experiences in the world and also is dependent on culturally based stereotypes (race, sex, mental illness) developed during preschool years (Corrigan and Watson 2007). Leichtman and Ceci (1995) conducted a study about delays in reporting events, stereotypes, and suggestibility. They found that children's stereotypes and influence by others can result in inaccurate memory of an event.

MEMORY AND TRAUMA

Children's memory for recalling traumatic incidents has been the subject of debate for many decades. Highly traumatic events are imprinted more than everyday routine events due to the level of emotionality and often the drama surrounding the event e.g. police involvement, injuries, removal of children from their parents. However, live courtroom testimony can be an emotionally traumatic experience for many children.

There is also a curvilinear relationship between very stressful events and less optimal memory performance. The risk of increased stress or recalling trauma is high. Low levels of stress illicit low levels of attention to memory. Moderate levels of stress can enhance recall. Higher levels of stress are predictive of lower levels of remembering (Ornstein 1995; Pezdek and Taylor 2002). The correlation between increased cortisol levels during stressful events is well documented. High levels of cortisol affect the hippocampus, thereby affecting memory retrieval (Quesada et al. 2012). However, stressful events can also cause imprinting due to the high emotionality of the event and therefore lead to stronger memories due to the personal meaning of the event.

Memory of public events, such as the September 11 terrorist attacks, are described as flashbulb memories. Memories are also anchored to events with high levels of trauma and stress. These memories are embedded like a photograph and are thought to be highly accurate and fixed due to overstimulation of the event (Segovia and Crossman 2012). Research has shown that retrospective accounts of traumatic events for persons with higher levels of posttraumatic stress disorder (PTSD) symptoms may be associated with amplified recollections of the precipitating events and may be more prone to alteration over time (Engelhard et al. 2008). Therefore, stress and trauma, especially if PTSD is present, can greatly affect the accuracy of a child's testimony in forensic settings. Alexander et al. (2005) found that the severity of PTSD symptomatology was positively associated with memory accuracy in adults recalling their past childhood sexual abuse.

Research in the area of child witnesses is limited to posttestimony reporting because randomized controlled studies are not possible or ethical. Tedesco and Schnell (1987) studied the effects of litigation based on the assumption that involvement in the court process further victimizes children. The authors sent questionnaires to victims of child sexual abuse and revealed that only 21% of the victims perceived that the questioning and investigation were harmful while 53% found it helpful. Court testimony and repeated interviews revealed more negative ratings.

The Academy of Child and Adolescent Psychiatry (AACAP) released a position paper in 1989 warning of the serious potential for trauma and serious stress to children involved in court proceedings. The position paper recommends modifications to allow children a safe way to participate in the legal system, such as limiting the number of interviews of child victims, coordinating court proceedings by single thorough, investigation shared between investigators and prosecutors, expedient court proceedings, modifications to hearsay and other evidentiary and courtroom restrictions, and assessment of child witnesses by forensic examiners.

REPEATED INTERVIEWS

There has not been consensus on the issue of repeated interviews of child victims. A study conducted by Bruck (2002) concluded that repeated interviews lead to errors in the forensic process. Other studies revealed that repeated interviewing increased the accuracy of testimony or had no adverse effect (Goodman et al. 1991; Baker-Ward et al. 1993). Pipe (1999) found that whereas information repeated across interviews was highly accurate, information reported for the first time after long delays was not.

INTERVIEWER BIAS

According to Bruck and Ceci (2002), the concept of interviewer bias (Ceci and Bruck 1995) is a defining feature of suggestive interviews. Interviewer bias is described as those interviewers who hold a priori beliefs about the occurrence of certain events and who mold the interview to maximize disclosures that are consistent with those prior beliefs. One hallmark of interviewer bias is the single-minded attempt by an interviewer to gather only confirmatory evidence and to avoid all avenues that may produce disconfirmatory evidence. Inconsistent or bizarre evidence is either ignored or interpreted within the framework consistent with the interviewer's hypothesis. Authenticity of statements is not challenged when it aligns with the interviewer's beliefs. Inconsistent statements are subject to repeated questioning designed to align the child's subsequent reports with the interviewer's initial beliefs.

RACE AND SOCIOECONOMIC

The research is lacking in considering race or socioeconomic status influencing suggestibility and false memory. Bruck (2004) synthesized 69 studies and found that language ability and creativity are consistently related to suggestibility. Race is often associated with intelligence and language. Given the disproportionate number of minority children in criminal proceedings (Vernon-Feagans 2002), child witness language skills is a concern when children are forensically interviewed.

GENDER

Bruck (2004) analyzed the result of 20 studies examining the possible link between gender and suggestibility. Only four studies found significant differences and the results were inconsistent. No definitive consensus has been reached answering questions of gender relationship of witnesses to suggestibility.

KNOWLEDGE ABOUT LEGAL SYSTEM

In international legal settings, studies have shown that children experience more distress when they lack knowledge of the legal system. Ben-Arieh (2007) found that adolescents in the Israeli legal system were subsequently more willing to cooperate with police when they had victim support through the legal process.

ANATOMICAL DOLLS

The use of anatomical dolls in child sexual abuse forensic evaluations continues to stir debate. Most research has led to negative and critical reviews for anatomical dolls for decades (Bruck 1995, 2000, 2009; Salmon 2001, 2011; Willcock 2006; Brown 2007, 2011; Poole 2011; Poole and Dickinson 2011; Otgaar 2012). Few authors support the use of anatomical dolls (Faller 2005; Anderson 2010; Hlavka 2010). Despite the long-standing controversy over the use of anatomical dolls in sexual abuse investigations, they continued to be used and are the subject of numerous appeals *Lee v. Lampert* (2011), *Kraus v. Taylor* (2013), *US v. Chaco* (2011), and *Spencer v. Peters* (2013). Due to the lack of consensus of the use of anatomically correct dolls, California has barred the admissibility of evidence collected through the use of anatomically correct dolls.

The use of non-verbal aids in forensic interviews has met with similar disagreements as the use of anatomically correct dolls. Several studies, Salmon (2012), Barton (2014),

Brown et al. (2012b) have cautioned against the use of non-verbal aids such as diagrams. Lyon (2012) recommended the use of non-verbal aids as a last resort after the disclosure section of the NICHD protocol and only when a subsequent interview is not practical or when delay endangers the child.

Special needs in child witnesses

INTELLECTUAL DISABILITIES

Children with intellectual disabilities are more vulnerable to abuse (Crosse 1993; Sedlak 1996a; Randall 2000; Balogh 2001; Hershkowitz et al. 2007; Reiter 2007) and are less likely to report the abuse or have their complaints investigated (Goldman 1994; Sharp 2001; Reiter 2007). Children with intellectual disabilities are also more suggestible than typically developing children (Henry 1999; Michel 2000).

Henry (2011) found lower perceptions of credibility for child witnesses with intellectual disability compared to typically developing child witnesses. Brown et al. (2012a) found that children with mild intellectual disabilities were as able as their mental age matches, but even though children with more severe cognitive impairments had qualitatively different competencies, they could be highly accurate in a supportive interview forensic setting. Further, more detailed responding is expected by mainstream children than those with intellectual disabilities (Gordon et al. 1994; Henry 2007, 2011).

Court testimony of children

PREPARATION

Lipovsky (1997) recommended the following goals to prepare children for court experiences: "to improve the child's ability to answer questions in court in the most accurate, complete, and truthful manner; to maximize the child's ability to be perceived as a credible witness; to minimize the likelihood that the child will suffer negative court-related consequences." Preparing a child does not mean coaching the child about how they should respond on the witness stand. Court preparation can include group classes in which the children might realize they are not alone in the process or individualized preparation by court personnel, mental health professionals, and volunteers (Finnegan 2002).

JURY PERCEPTION

Buck et al. (2014) studied the knowledge of jury-eligible college students, investigative interviewers, forensic psychologists, and public defenders with regard to interviewing children. Jury-eligible students were the least knowledgeable. Both investigative interviewers and public defenders performed better than jury-eligible students, but lacked substantial knowledge about the research on interviewing children on certain topics (e.g., using anatomically detailed dolls); forensic psychologists were the most knowledgeable.

CROSS-EXAMINATION

Most courts prefer to protect children from testifying in court because of the inherent risks and stress of court proceedings. Cross-examination is a stressful experience for even a seasoned expert witness. The effect of cross-examination-style questioning of child witnesses was studied by O'Neil and Zajac (2013a) concluded that cross-examination-style questioning is particularly detrimental to obtaining accurate event reports from children. Fogliati and Bussey (2015) found that cross-examination led children who were not coached to recant their initial true allegations and reduced children's accuracy for neutral events. In another study by Fogliati and Bussey (2014) they found that cross-examination may not be the most effective procedure for eliciting truthful testimony from children aged between 5 and 8 years. Stolzenberg (2013) found that pressing child witnesses to answer questions they are initially reluctant to answer is not an effective practice.

Children also risk losing credibility because they often change their incorrect and correct answers in response to cross examination. Zajac (2003) found that child witnesses rarely asked for clarification and often attempted to answer questions that were ambiguous or did not make sense, and 75% changed at least one aspect of their testimony. Cross-examination-style questioning is inappropriate for young children.

Special considerations for child sexual abuse

Most of the research of children's testimony in court has focused on child sexual abuse victims. Children's testimony often involves traumatic and intimate experiences which they have witnessed or been a victim of. Whitcomb (2003) found that children have multiple fears about testifying in court, and identified four factors as most frightening:

1. Facing the defendant
2. Describing details of the abuse
3. Testifying in front of strangers
4. Not understanding all the questions asked

There are typically two types of expert testimony challenged in child sexual abuse cases: (1) general testimony describing behaviors and other characteristics commonly observed in sexually abused victims ("profile" testimony); and (2) particularized testimony concerning the alleged victim's credibility. Numerous courts have ruled in favor of expert witness admissibility in child abuse cases: *State v. Sloan* (1995), *Barlow v. State* (1998), *State of Ohio v. Gersin* (1996).

Child witness interview techniques and guidelines

There are many risks to the forensic process if children are not interviewed in formal forensic settings such as police

interviews, or by forensically trained medical or mental health professionals. Mandated reporters of child abuse are legally required to report reasonable suspicion of child abuse. This low threshold is meant to ensure that the baton for further investigation is handed to government agencies specializing in forensic investigations of child abuse. In reality the majority of initial disclosures of child abuse are to a medical professional as part of a routine evaluation or treatment (Suddath 2003) or schoolteachers. Pediatricians who are the first witness to the disclosure of child abuse are rarely forensically trained. By nature they are inquisitive and attempt to gather more details about the abuse. However, the information they gather is often not recorded in a manner compatible with the rigors of the legal system and interviews are rarely documented that include exact quotes of the questions and responses.

Comprehensive pretrial interventions utilizing a practice–feedback approach help children to give more accurate testimony when cross-examined (O'Neil and Zajac 2013b). Many elements need to be in place to prepare children for forensic interviews and maximize the utility of the information collected. Ideally, the timing of the interview is best done as proximate to the events or events, especially since children's memories are fluidly changing and developing. Additionally, the risk of contamination by external influences such as peer or family pressure increases. In reality there is often a significant time lag between the event in question and forensic interviews. Selecting age-appropriate interview procedures requires developmental sensitivity (Saywitz 1998, 2013).

In order to limit the number of interviews, it might be possible to gather questions from different sources such as defense attorneys and prosecutors before proceeding with the interview. McGough (1996) suggested an extension of this interview process in which the defense and prosecuting attorneys observe the interview and interject their questions during breaks. The setting of the forensic interview might also help alleviate anxiety and maximize factual information gathering to optimize the forensic process.

The American Professional Society on the Abuse of Children Practice Guidelines Series (2002) recommend interviewing children in Child Advocacy Centers. Traditionally child interviews have been conducted at police stations, child protective services offices, homes, and schools. All of these settings have inherent problems that might increase the anxiety or compromise evidence gathering. Although the presence of an adult support person might alleviate anxiety, it is recommended that forensic interviews are conducted alone with the child (Poole and Lamb 1998). In the courtroom the presence of a support person, transitional object, such as a stuffed animal or toy, and closed-circuit testimony might be beneficial for the child witness.

Forensic interviews are part of the evidence in many cases. A record of the interview by audiotaping, videotaping, or both, provides optimal evidence (Bertel 2012). Some states, such as Idaho and Utah, mandate that all investigative interviews of suspected child abuse must be audio or video recorded (Idaho Code 2011; Utah Code 2011). At least 12 states have statutes that discuss the admissibility of video-recorded forensic interviews as evidence in criminal cases of child abuse (Kellogg 2005).

GUIDELINES

The area of child sexual and physical abuse has been well researched over the past 30 years. Many organizations have set forth guidelines for forensic interviews of children. In 2000, The *Eunice Kennedy Shriver* National Institute of Child Health and Human Development (NICHD) developed a protocol for child sexual abuse allegations called the NICHD Investigative Interview Protocol. The NICHD protocol has been translated into multiple languages and is available online.

Court testimony of a child: Role of the mental health professional

Mental health professionals are often experts or consultants at many levels of the legal system when children are involved. Their roles are varied, from treatment provider to court-appointed expert to consultants and educators to attorneys, families, judges, and law enforcement. They might provide expert testimony about children's testimony in court or give opinions about the psychological impact on the child with respect to the event or events they witnessed, experienced, or are living, as in child custody disputes.

Experts can opine on the competency of a child to testify, e.g., in juvenile delinquency cases as defendants or in civil or criminal cases as witnesses. If the child is deemed competent to provide testimony, the mental health professional might be used as a consultant to the attorneys examining or cross-examining the witness. They might evaluate whether the child should testify in court or through closed-circuit television. They might prepare the child for testimony and treat anticipatory anxiety prior to and after testimony.

Competency is determined by the judicial officer in most cases. However, forensic mental health experts are often asked to evaluate on competency issues for children in court. The standards for competency to testify are similar to those of adults and involve perception, memory, and truth–lie competency; the understanding of the difference between the truth and a lie and the duty to tell the truth (Myers 1993; Lyon 2011).

Competency is different than credibility. Only the triers of fact (judge and/or jury) make the ultimate determination of the credibility of a witness. Experts might opine as to the consistency of statements made by a child in an investigation and relate them to the multiple developmental facets of child witnesses. In all forensic settings the expert's role is to give neutral, balanced opinions based on evidence. They should describe strengths and weaknesses of the child's testimony with respect to the aspects of the case, supported by

research if applicable. The expert might opine on whether the method of forensic interviewing met standards and was valid or describe the flaws in the interview technique (Poole et al. 2015).

The importance of expert testimony in child sexual abuse cases was studied by Buck et al. (2011). They found that mock jurors were more likely to render guilty verdicts if the interview quality was good versus poor. Further expert testimony increased mock jurors' knowledge about child witnesses. Expert testimony on proper interview techniques may bolster the prosecution in cases where the child was interviewed in a high-quality manner.

SUMMARY

Children can be effective witnesses in forensic investigations. Research is consistent that even very young children have accurate recall of events and can assist authorities in making accurate determinations of the truth in the justice system. The general core difference between adult and child witnesses is the developmental trajectory of children compared to the relatively static cognition of adults. Research has primarily centered on very young or young children under 6 or 7 years old. There is far less research material on latency-aged children or adolescents as witnesses, most likely due to the rapid upward gradient of cognitive and memory changes in very young and young children. Studies of older children are often compared to adults and have found less variability in their suggestibility than with younger children. The social influences during adolescence such as peer pressure, emerging sexuality, and views on authority figures are areas for future research. Additionally, in the rapidly changing era of social media in which adolescents are almost universally ensconced, the influences from numerous media are a potential area for studies of adolescents in the legal system.

The area of interviewing techniques and protocols has gained greater definition over the past 20 years. Numerous protocols have been developed, all of them with a common goal of obtaining valid, uncontaminated, admissible evidence by trained forensic evaluators to assist in the pursuit of justice. Further refinement and possibly merging of the numerous interview protocols is likely. However, it is possible that all the protocols and guidelines have validity and are the result of the mission of the respective legislative bodies, associations, agencies, and academies.

The subject of witness in child sexual abuse cases overwhelms the research data. While child sexual abuse is a serious and sensitive issue, children are often involved in legal proceedings in many other arenas: civil litigation, dependency, and other nonsexual abuse criminal matters such as domestic violence. There is little research on child witnesses in many of these areas.

Children are now more protected in court settings with the advent of closed-circuit television to provide testimony, but also by more refined investigative interviewing techniques. In 2012, California introduced rules of court to allow evidence from children in family law cases if they wanted their voice to be heard. Given this recent change, there is little research available studying the pros and cons of children being more intricately involved in their parents' divorce.

There is plentiful data about child witnesses with intellectual disabilities, but there is little research available regarding the effects on child witnesses with mental illnesses when they are in the legal system. Children with mental illness are also a vulnerable group and are at risk of abuse.

Further, the long-term effect on children involved in the legal system is an area that is often overlooked and poorly researched. In civil litigation, literally the million-dollar question is the long-term effects of trauma (personal injury or abuse) and how that relates to damages. Such studies are often difficult and long term, making it almost impossible to conduct due to ethical considerations, but also due to the infinite number of variables that might affect a person's path through life after experiencing trauma as a child.

Neuropsychological assessment of children and adolescents: Clinical and forensic considerations

LAURA J. PHILLIPS AND ANN C. MARCOTTE

INTRODUCTION

Neuropsychology is the branch of psychology devoted to the scientific study of brain–behavioral relationships and their clinical applications. Neuropsychology emerged as a distinct discipline within psychology in the 1950s (Benton 2000), although it was not until 1996 that the American Psychological Association recognized clinical neuropsychology as an official subspecialty in psychology (Barr 2008). Similar to psychiatry and neurology, research and clinical practice in neuropsychology fall within two broad domains: adult and pediatric. Pediatric neuropsychology is the branch of neuropsychology focusing on the applied understanding of neurobehavioral functions of the infant, child, and adolescent (Baron 2004). The number of neuropsychologists who self-identify as specializing in pediatrics, either solely or in combination with adult work, has also grown steadily over time, yet represents less than 40% of the neuropsychology community (Yeates et al. 2010; Sweet et al. 2011).

Most of what was known about human brain–behavior relationships was initially derived from studies of adult brains. Over the past several decades, the scientific community has come to recognize that children's brains are anatomically and functionally distinct from those of adults (Waber et al. 2007, 2012), and brain–behavior relationships in developing children are qualitatively and quantitatively different (Baron 2004). Understanding the pattern of normal brain development and its relationship to the emergence and regulation of complex behaviors and cognition in typically developing children and adolescents has been a focus of research in pediatric neuropsychology, as well as in developmental and cognitive psychology. Advances in medicine have contributed to increased rates of survival and improved outcomes for children with specific brain insults and neurological diseases, allowing for more in-depth study of genetic, congenital, and acquired brain abnormalities and their relationships to cognition and behavior. Similarly, technological advances in brain imaging have provided increasingly more sophisticated methods for studying brain development and understanding the negative influences of injury, disorder, and disease on a child's neurological functioning (Baron 2010).

As the field of neuropsychology has continued to expand, so has the reach of pediatric neuropsychologists, who now contribute to research and theoretical formulation, test development, and clinical evaluation and treatment/educational planning for patients. Pediatric neuropsychologists work in a range of settings, including university teaching and research settings, inpatient and outpatient medical settings, and private practices. The forensic arena is yet another area in which pediatric neuropsychologists are becoming increasingly involved. In this chapter, we outline the purpose and content of pediatric neuropsychological evaluations, both in clinical and forensic practice. We will then describe the contributions such evaluations can offer civil and criminal forensic cases involving children and adolescents.

THE CLINICAL PEDIATRIC NEUROPSYCHOLOGICAL EVALUATION

The seminal book, *Neuropsychological Evaluation of the Child* (Baron 2004), provides an excellent, in-depth overview of the pediatric clinical neuropsychological evaluation. In the broadest sense, clinical neuropsychological evaluations of children and adolescents are typically sought to delineate underlying neuropsychological factors affecting a child's behavior, social/emotional functioning, and/or pattern of learning, with an emphasis placed on defining the child's unique profile of strengths and weaknesses. The results are then used to guide future treatment

and/or educational planning. A clinical pediatric neuropsychological evaluation includes direct behavioral observation of the child during testing as well as the administration of objective test measures. The evaluation process also includes a review of provided medical and academic records. A parent(s) or caretaker interview is performed to obtain the child's developmental, medical, behavioral, social/emotional, and educational histories, as well as the family medical, psychiatric, and educational histories. Such ancillary information plays a vital role in case conceptualization in child and adolescent neuropsychological evaluations.

As noted by Brooks and Iverson (2012), "No other specialty has developed, normed, and validated measures of cognitive ability in the same manner as neuropsychologists" (p. 66). This speaks to the strong scientist–practitioner tradition of clinical neuropsychology. A detailed review of principles of psychometric theory and issues pertaining to neuropsychological test development, test selection and use, and factors that can affect the interpretation of neuropsychological tests is beyond the scope of this chapter; the interested reader is referred to Bush, McAllister, and Goldberg (2012) and Brooks and Iverson (2012) for reviews on these topics. Measures selected for inclusion in the clinical neuropsychological battery to assess and quantify brain–behavioral relations vary as a function of the child's age and the specific referral question(s) of the case. Testing measures have been developed and normed for a range of ages, and tests are selected to allow for interpretation of a child's performance in the context of development through the use of age-based normative data. A clinical pediatric neuropsychological examination most typically includes measures of intelligence, academic functioning, receptive and expressive language, sensory and motor functions (including visual perception, visual–spatial organization, and fine motor dexterity and speed), learning and memory, attention and concentration, and executive functions. Intellectual and academic measures are included in pediatric neuropsychological evaluations to allow for a determination of possible learning disorders, which is a common referral question for testing. Depending on the case, a testing battery may also include objective measures of psychological and behavioral functioning that can include self-ratings completed by the child, in addition to standardized parent and teacher rating measures of the child. For cases in which a diagnosis of intellectual disability is being considered, standardized measures of adaptive behavioral functioning must also be included in the testing battery.

Referrals for clinical pediatric neuropsychological evaluations are sought for a number of reasons and from varying sources. School personnel may refer a student for a comprehensive clinical neuropsychological evaluation when learning and/or behavior problems are observed in the academic setting. Such referrals often come after a school district has completed its own series of special educational evaluations, from which questions pertaining to the specific nature of the student's difficulty with success in the academic setting remain to be answered. The clinical neuropsychological evaluation can explore possible neurocognitive, psychological, and behavioral factors affecting a child's school functioning in greater depth, in a more integrated manner, and with a greater appreciation for child development than is typically undertaken in school-based evaluations.

Parents are yet another common referral source for clinical pediatric neuropsychological evaluations. Children can present differently in the home environment than they do in school due to different demands being placed on them; thus, behaviors that could potentially signal a problem may be seen at home but not at school (and vice versa). Parent-based referrals also arise when parents seek an independent neuropsychological evaluation of a child when they are dissatisfied with the conclusions drawn and services put into place after a school district has completed its own evaluations or when a school district denies a parent's request for testing.

Medical personnel in a range of disciplines refer children and adolescents to a neuropsychologist to examine the acute or long-term sequelae of disease, disorder, or injury on brain functioning and to assist with treatment and/or educational planning. The past several decades have seen increasingly more sophisticated and sensitive means of understanding the negative impact of neurological insult. Although the site and extent of a brain lesion can be identified on imaging, the image does not clarify the nature of residual behavioral and cognitive strengths and accompanying areas of weakness, whereas a clinical neuropsychological evaluation can provide such important information (Lezak et al. 2012). Researchers in pediatric neuropsychology have studied the neurocognitive sequelae of many different pediatric medical conditions (i.e., premature birth, genetic disorders, spina bifida, brain tumors, epilepsy, acute lymphoblastic leukemia, head injuries), and there is a growing body of literature that provides some of these disorders and diseases a specific context within which a child's neuropsychological testing results can be conceptualized. (See Yeates et al. 2010 for reviews of the neuropsychological correlates and developmental sequelae of several of these medical conditions.) Challenges related to medical referral questions arise given the developing nature of the child and adolescent brain. Neuropsychologists may be asked to monitor and predict a child's recovery from a neurological insult, but such recovery can be heavily affected by many factors, such as age of insult, premorbid functioning, socioeconomic, family, and other environmental conditions. The evolving state of a child's brain further means that some areas of potential cognitive and/or behavioral impairment, especially those associated with the frontal lobes, such as executive functioning, may not be evident until later when the child enters that phase of brain development (Dennis 2000).

THE FORENSIC PEDIATRIC NEUROPSYCHOLOGICAL EVALUATION

Neuropsychologists increasingly play a role in the forensic arena. Since the 1980s, the value of clinical

neuropsychologists in the courtroom has become more widely appreciated (Hartlage and Stern 2010), and the number of litigated cases involving neuropsychological experts has increased dramatically over time (Taylor 1999; Sweet and Giuffre Meyer 2012). Evaluations sought for clinical purposes initially can later evolve into forensic cases, with the treating neuropsychologist sometimes placed into the role of an expert fact witness in later legal matters. Alternatively, neuropsychologists can be retained for the specific purpose of examining an individual as part of a forensic case, thereby performing the evaluation as an expert witness to answer a legal question (Sweet and Westerveld 2012). In all forensic neuropsychological evaluations, as in forensic psychiatric evaluations, professional ethical issues including competency and scope of practice, consent and assent for testing, and limits of confidentiality differ from those of clinical evaluations and must be addressed (Bush et al. 2012).

There are similarities between clinical and forensic pediatric neuropsychological evaluations. In a forensic case, the neuropsychologist is typically provided with extensive records gathered by the legal team about the case, which are reviewed and considered in rendering an opinion. As part of the forensic neuropsychological evaluation process, the child's parent(s) or caretaker is also typically interviewed to obtain information about the child. The forensic neuropsychological evaluation frequently assesses the same areas of functioning as examined in a clinical neuropsychological evaluation, described above.

There is a critical need in forensic evaluations, however, to evaluate the examinee's effort toward testing directly (Heilbroner et al. 2009). Conclusions drawn from a neuropsychological evaluation depend on the validity of the data collected, and that validity is largely dependent on the examinee's honesty and effort in test taking. A negative response bias, noncredible effort, "faking bad," and feigning of symptoms can arise in the context of forensic pediatric evaluations, as examined children may perform in a suboptimal manner knowingly or unknowingly (Sweet and Westerveld 2012). Bush et al. (2012) have identified several reasons children may give less than perfect effort in testing, including anxiety about being evaluated, the presence or absence of a parent or other familiar adult in the room, possible oppositional behavior, a lack of understanding or appreciation of the testing and of the importance of trying one's best, instruction by others to do poorly, and a poor fit between the child and the examiner.

Tests specifically designed to measure testing effort, referred to as symptom validity tests, have been developed for use with adults, and the use of symptom validity tests with children has been the topic of recent research (Kirkwood 2012). As reviewed by Kirkwood, some "stand-alone" adult-based symptom validity tests with preliminary research support for use in pediatric populations include the Test of Memory Malingering (Tombaugh 1996), Word Memory Test (Green 2003), Medical Symptom Validity Test (Green 2004), and the Rey Fifteen Item Test (Rey 1964). See Table 45.1 for a description of these measures. Several self-report measures used with children and adolescents in evaluations were developed with embedded internal reliability and validity indices, allowing other ways to examine these behaviors. Examples of such tests include the Minnesota Multiphasic Personality Inventory (MMPI)-Adolescent, Personality Assessment Inventory—Adolescent, Personality Inventory for Youth, Behavior Rating Assessment System for Children—Third Edition, and the Trauma Symptom Checklist for Children.

Table 45.1 Examples of stand-alone symptom validity tests used in pediatric populations

Test and brief description	Time required (minutes)	Age effects minimal by
Fifteen Item Test: 15 items shown briefly and then drawn from memory	5	≥11 or 12 years
Medical Symptom Validity Test: Computerized forced-choice 10 word-pairs verbal memory test	5	≥8 years or ≥third grade reading level
Test of Memory Malingering: 50-item forced-choice visual recognition test	15	≥5 or 6 years
Word Memory Test: Computerized forced-choice 20 word-pairs verbal memory test	15	≥11 years or ≥third grade reading level

PEDIATRIC NEUROPSYCHOLOGY IN THE FORENSIC SETTING

Pediatric neuropsychologists can make meaningful contributions to both civil and criminal proceedings involving children and adolescents. Neuropsychologists often provide evaluations independent of other professionals who may also examine the same examinee, such as a forensic psychiatrist. In addition to their own evaluations, the results of the forensic pediatric neuropsychological evaluation may be of assistance to forensic psychiatrists in aiding case conceptualization and forming opinions. Some examples of civil and criminal cases in which a pediatric neuropsychologist may be asked to participate are described below.

Examples of pediatric forensic neuropsychological evaluations in civil cases

MEDICAL MALPRACTICE

When central nervous system (CNS) dysfunction is alleged to have resulted from medical error or negligence, pediatric neuropsychologists are well suited to rendering opinions about the cognitive and behavioral status of such children, as well as about possible causes of impairments given their understanding of brain–behavior relationships and knowledge of the range of effects CNS impairment can pose on normal development (Baron and Morgan 2012). Medical malpractice cases that are referred to a forensic pediatric neuropsychologist for evaluation can involve injuries allegedly sustained during and/or shortly after birth. For example, hypoxia, or oxygen deprivation during the perinatal period has been associated with neurodevelopmental sequelae that range from subtle language and learning difficulties to more severe motor impairment and mental retardation (Armstrong-Wells et al. 2010). Premature birth can also be associated with a range of cognitive and behavioral sequelae (Taylor 2010a, 2015; O'Shea et al. 2013). While motoric difficulties associated with birth or perinatal injuries tend to be evident sooner in a child's development, associated cognitive and behavioral deficits, such as learning or attention disorders, may not become apparent until the child is older. Malpractice suits can also arise from alleged negligent medical care provided to children after birth that can affect CNS functioning. For example, CNS problems can arise from surgical complications, such as problems during surgery with the administration of anesthesia such that the flow of oxygen to a child's brain was disrupted.

Prenatal exposure to prescription medications taken during pregnancy can be the basis for other medical malpractice lawsuits, particularly if it becomes known that the prescribing physician was aware of a medication's risk to the developing fetus. Attention is now being given to possible long-term neurodevelopmental effects associated with in utero exposure to certain prescription medications, such as neuroleptic medications (Meador et al. 2007) and antidepressant medications (Casper et al. 2003; Galbally et al. 2011).

TRAUMATIC BRAIN INJURY (TBI)

Another common context in which a forensic pediatric neuropsychologist becomes involved in civil legal proceedings arises when a child or adolescent has sustained an acquired brain injury that was the alleged result of trauma from an accident (e.g., motor vehicle accident, negligent fall) for which an unrelated party is responsible. There is an extensive and growing body of research on the neuropsychological consequences of pediatric TBI by age of insult, as well as across injury severity gradients (for reviews, see Babikian and Asarnow 2009; Taylor 2010b; Yeates 2010, 2012; Gioia et al. 2012). TBI, particularly of moderate to severe impairment, can produce long-term deficits in a variety of cognitive and motor domains, and such injuries can be related to declines in school performance with associated increased risk of grade retention, placement in the special education system, and other indicators of academic difficulties (Ewing-Cobbs et al. 1998; Taylor et al. 2003). TBI can also result in problems with social, emotional, and behavioral functioning, and children and adolescents who have incurred a TBI are at higher risk for psychiatric disorders, especially attention deficit/hyperactivity disorder (ADHD; Max et al. 2012). A TBI sustained in childhood can also affect a variety of functional outcomes in later life. For example, children who sustained moderate to severe TBI exhibit lower educational attainment, lower employment and reduced occupational status, increased risk for psychiatric disorder, and reductions in functional independence and perceived quality of life (Cattelani et al. 1998; Nybo et al. 2004; Anderson et al. 2009; Anderson et al. 2010).

Discerning post-TBI changes in a child's ability to function requires knowledge of normal development, the nature of the TBI, cognitive sequelae that are characteristic of the particular brain insult, and appropriate measurement of behavioral, cognitive, and academic functioning (Max et al. 2012). Pre-TBI cognitive and behavioral levels of functioning must be ascertained to determine if the child shows deviations from previous functioning due to the injury. Such information can sometimes be gleaned from a review of educational records, as well as retrospective information provided by the patient, family members, and teachers. A thorough developmental history can also provide the neuropsychologist with important information about the child's premorbid functioning that includes premorbid learning, attentional, psychiatric, or behavioral disorders; family risk factors; and the family environment (Gioia et al. 2012). Neuropsychologists may further be able to use a variety of current information to estimate a child's premorbid functioning. (See Max et al. 2012 for a review of such factors.)

CHILD CUSTODY CASES

There can be a role for a forensic pediatric neuropsychological evaluation in some child custody legal cases. Although it is more typical for the parents involved in such cases to undergo psychiatric, psychological, and/or neuropsychological evaluations to determine their ability to parent, neurocognitive and/or behavioral characteristics of the child involved in such cases may also have direct bearing on such cases. A child may present with suspected or known cognitive and/or behavioral conditions that may affect the ability of a parent to care for the child. A forensic pediatric neuropsychological evaluation can provide important information about a child involved in a custody battle, which can be considered by the court in determining custody arrangements that are in the best interest of an affected child or adolescent.

DUE PROCESS/IMPARTIAL HEARINGS IN THE SPECIAL EDUCATION SYSTEM

Forensic pediatric neuropsychologists can also play a role in due process hearings under the auspices of special educational laws. (See Hahn and Morgan [2012] for a review of special educational laws and due process hearings.) Psychiatrists can become involved in such school-based legal actions when a student's psychiatric and/or behavioral functioning affects learning and behavior in the school setting, and requires the provision of special educational services. Due process refers to the specific set of procedures used to resolve disagreements between families and a school system about decisions regarding a student's identification, evaluation, educational placement, and/or the provision of a free, appropriate, public education as delineated by special educational laws. Neuropsychologists may become involved in such matters when parents seek an independent pediatric neuropsychological evaluation to assist in a due process hearing, where, based on the findings of the independent evaluation, the neuropsychologist renders professional opinions as to the educational needs of the student.

Pediatric forensic neuropsychological assessment in criminal cases

The issue of competence refers to one's capacity to distinguish right from wrong and to control one's actions accordingly. Historically, psychiatrists and clinical psychologists have been the mental health professionals rendering opinions in court proceedings regarding the competency of a defendant. Factors considered in determining mental competency can include maturity of thought, the capacity for forethought, the capacity for problem solving, the ability to anticipate the outcome of one's action, the ability to identify and distinguish between multiple choices, and whether a person was reacting to a threat (Rosado 2000). Each of these factors is considered in determining competency; however, each can be affected by other factors. One mitigating factor is age at the time of the offense or time of trial. The emergence of many of the behaviors considered in determining competence parallel brain development, particularly that of the frontal lobes, which is the region of the brain responsible for our capacity to think abstractly, anticipate consequences, plan, and control our impulses. The frontal lobes continue to develop into young adulthood (Sowell et al. 1999; Sowell et al. 2001).

Another factor affecting competence is limited intellectual functioning. By definition, an individual with intellectual disability has deficiencies in reasoning, problem solving, planning, abstract thinking, judgment, academic learning, and learning from experience, as well as limitations in adaptive functioning (APA 2013). Evaluation of intellectual and adaptive functioning is required to render such a diagnosis, and documentation of intellectual disability can have a significant effect on court proceedings.

With an increasing understanding of the role brain function plays in determining behaviors, attorneys have increasingly turned to neuropsychologists to address the specific issue of limited competence based on impaired cognitive function (Hartlage and Stern 2010; Sweet and Westerveld 2012). It has been recognized that brain injuries can be associated with higher incidence of juvenile delinquency and the commission of violent crimes (Williams et al. 2010; Davies et al. 2012). Children with some types of learning disabilities and other neurodevelopmental disorders, such as ADHD, have been described as being at increased risk for involvement in the juvenile justice system (Gordon and Moore 2005; Gordon et al. 2012). Thus, delineating how an acquired or congenital brain disorder may affect behavior and learning through a forensic pediatric neuropsychological assessment can provide additional important information to assist in rendering determinations of the competence of a juvenile in the legal system; in some cases, this information can also serve as a mitigating factor in determining sentences (Hartlage and Stern 2010). Specific neuropsychological conditions that might be the focus of a forensic pediatric neuropsychological evaluation in criminal cases include neurodevelopmental disorders and traumatic brain injury.

NEURODEVELOPMENTAL DISORDERS

Studies estimate that children with severe emotional disturbance, learning disability, intellectual disability, and ADHD are overrepresented in the juvenile justice system. Reported estimates of such neurodevelopmental disorders in the juvenile justice system range from 30% to 70% (Rutherford et al. 1985; Murphy 1986; Casey and Keilitz 1990; Quinn et al. 2005), as compared to roughly 13% of the general school-aged population (U.S. Department of Education, National Center for Education Statistics 2013). As reviewed by Malmgren et al. (1999) and Mallett (2011), several theories have been proposed to account for the higher risk of juvenile court involvement for students with learning disorders, which include the school failure hypothesis, the differential treatment hypothesis, and the susceptibility hypothesis. The susceptibility hypothesis posits that youths with learning disabilities have cognitive, neurological, and intellectual difficulties that contribute to delinquent and antisocial behavior, and place them at risk for involvement in the juvenile justice system. Students with ADHD are also overrepresented in the juvenile court system. Inattention and impulsivity are the defining observable criteria for ADHD, but children and adolescents with ADHD can also show significant impairment in executive functioning skills (Barkley 1997), which include the ability to brainstorm multiple solutions to problems, plan effectively, reason abstractly about the consequences of actions, and self-monitor behavior. Thus, problem-solving capabilities can be limited in children and adolescents diagnosed with ADHD, and this may contribute to their being more likely to engage in criminal behavior than neurotypical peers (Brier 1989). Children and adolescents with language impairments have been reported to be more likely to engage in delinquent behaviors (Brier 1989). It has been proposed that the link between language

deficits and delinquent behavior is due to immature "private speech" (defined as speech spoken to oneself with the purpose of self-guidance and behavioral regulation), which may in turn result in deficiencies in self-regulation (Camp 1977; Camp et al. 1977) and social problem solving (Kazdin 1987).

TRAUMATIC BRAIN INJURY

Several research studies have suggested a link between TBI and violent and nonviolent criminal behavior (Grafman et al. 1996; Sarapata et al. 1998; Freedman and Hemenway 2000). The prevalence rate of self-reported TBI of any severity among violent offenders has been reported to range from 60% to 87% (Slaughter et al. 2003; Schofield et al. 2006; Williams et al. 2010). Studies have suggested that individuals with histories of TBI are at increased risk for engaging in violent or aggressive behavior (Rosenbaum and Hoge 1989; Grafman et al. 1996) and for committing crimes that lead to arrest following the injury (Brooks et al. 1986; Hall et al. 1994). From a neurological perspective, the link between TBI and criminal behavior is often hypothesized as related to impairment in the frontal lobes of the brain. Injury to the frontal lobes has been associated with loss of control over subcortical and limbic structures that are involved in primitive impulses (Grafman et al. 1996). Lesions in these areas can therefore affect one's reasoning, judgment, impulse control, and social perception, and they can also affect mood and emotional regulation. Adults who have had a TBI with frontal lobe involvement may misperceive social interactions, make poor social judgments, overreact to provocative stimuli, or lash out impulsively (Damasio et al. 1990; Grafman et al. 1996; Turkstra et al. 1996, 2003).

A link between TBI and criminal behaviors in youth has been suggested as well (Williams et al. 2010; Davies et al. 2012). Williams and colleagues (2010) conducted a study that involved collecting the self-reported histories of TBI, criminal behavior, mental health, and substance use of 147 male offenders ages 11–19 years old. TBI with loss of consciousness was reported by 46% of the sample, while possible TBI was reported by another 19.1% of the sample. A recent study using meta-analysis methods was undertaken to examine the relationship between TBI and juvenile offender status (Farrer et al. 2013). Analyzing nine published studies, approximately 30% of the juvenile offenders were found to have had a history of TBI. Of the five studies included in the meta-analysis that included a control group, analyses suggested that the juvenile offenders were significantly more likely to have sustained a TBI as compared to controls, suggesting a relationship between TBI and juvenile criminal behaviors.

SUMMARY

As the field of pediatric neuropsychology continues to grow, both in science and practice, it will continue to provide a unique perspective to child and adolescent forensic cases. Knowledge gained in pediatric neuropsychological research on normal brain development, as well as the cognitive and behavioral profiles associated with congenital and acquired neurological conditions, will allow for a greater understanding of complex brain–behavioral relationships and their emergence in childhood and adolescence. This information can help to improve the quality of forensic work conducted in the context of civil legal actions, including medical malpractice, cases involving pediatric brain injuries, and school-based legal hearings. Such knowledge may further broaden our understanding of factors associated with juvenile criminal actions that may be of importance in forensic neuropsychology and psychiatry in criminal cases. Advances in testing methods, especially with regard to symptom validity testing in children and adolescents, will also serve to improve the validity of clinical and forensic evaluations.

Assessment and treatment of adolescent sex offenders

LISA MURPHY, J. PAUL FEDOROFF, AND GREGG DWYER

INTRODUCTION

Despite crime statistics that indicate adolescents play a significant role in sexual offense rates and can vary psychopathologically from adult offenders, research on adolescents who sexually offend (often referred to in the literature as an adolescent sex offender or ASO) is largely limited in comparison to studies of adult sex offenders. Available data reveal a wide range of estimates about ASO's incidence and prevalence. For example, one study estimated that approximately one-third to one-half of known sexual assaults against a child are committed by an adolescent offender (Prentky et al. 2000; Finkelhor et al. 2009). Official statistics have indicated that 12.5% of all arrests for sexual assault and 14% of arrests for other sex offenses involve ASOs (U.S. Department of Justice 2009). According to Snyder (2000), juveniles account for 23% of all sex offenders. When broken down by victim age, adolescents are reported to account for 4% of sex offenses against adults and 33% of sex offenses against children. When examining child victims, 40% of adolescent perpetrated sex offenses are against victims under age 6 (Snyder 2009). In Ybarra and Mitchell's online survey study (2013) of 1058 youth aged 14–21 years old, 1 in 10 (9%; $n = 108$) self-reported sexual perpetration ranging from unwanted kissing, touching, or other unwanted sexual contact (8%; $n = 84$) to completed rape (2%; $n = 18$).

Research on age at first offense has indicated a range up to 50% for the number of convicted adult sex offenders reporting that their first sexual offense occurred in adolescence (Abel et al 1985; Abel et al. 1993; Rasmussen 2004). Recidivism is addressed later in the chapter, and those rates vary from self-reporting data. Another study reported people under age 20 years account for nearly 50% of all incidents of sexual aggression in the United States (Lowenstein 2006). In addition, some adolescent sex offenders have reported initially engaging in problematic sexual behaviors in early childhood (Burton 2000). Another study estimated one out of eight sex offenders are under the age of 12 (Finkelhor et al. 2009). Ybarra and Mitchell (2013) found age 16 was the most common age of first offence.

Adolescents who sexually offend are an important subgroup of offenders providing important information about the onset and early course of problematic sexual interests and behaviors. As addressed elsewhere in this text, the sexual abuse of children, whether perpetrated by adults or adolescents, can cause severe physical and psychological trauma to the victim. Research on the characteristics and offense patterns of ASOs will contribute to our understanding of the onset and course of the paraphilias and to improved assessment, management, and treatment of sex offenders and potential sex offenders of all ages. Of particular importance is the need for a preventative approach in which adolescents with sexual interests in criminal activities are successfully identified and treated prior to the commission of any real-life offenses. By identifying the characteristics of people in danger of becoming ASOs, the field may move from offering correction and rehabilitation to offering primary prevention and treatment to enhance noncriminal, healthy, and fulfilling sexual interests and behaviors (Lowenstein 2006; Fedoroff 2016).

This chapter reviews ASO behavior and addresses associated characteristics and offending patterns. Similar to adult sexual offenders, it has been widely noted that ASOs are a heterogeneous group, with many potential factors contributing to their problematic sexual interests and nonconsensual behaviors (Vandiver 2006; Van Wijk et al. 2006; Robertiello and Terry 2007). Like other adolescent offenders, ASOs often have varied familial problems including a history of neglect, physical abuse, and sexual victimization (Seto and Lalumière 2010). They have been noted to have higher rates of behavioral problems and difficulties in school, various psychopathologies, increased feelings of social isolation, and a tendency toward offending in general (Lowenstein 2006; Vandiver 2006). These factors are examined along with information on sentencing patterns, the

utilization of treatment approaches, and recidivism rates associated with ASOs.

DEFINITIONS AND CONCEPTS

Table 46.1 provides the authors' definitions for terms used in this chapter. These definitions may not be the same as those used in other publications. This fact highlights the caution needed when reviewing studies involving ASOs, because even the definition of what an "adolescent" is can vary.

LIMITS TO NORMALITY IN ADOLESCENT SEXUAL BEHAVIOR

When examining the issue of adolescent perpetrated sexual abuse, it is important to acknowledge that there is a wide range of sexual experience and exploration that is part of healthy adolescent experience. Cultural influences play a significant role in the determination of "normal" healthy sexual interests and activities. Behaviors that are considered atypical or problematic in some cultures may be commonplace in others. Within a given culture, familial and social factors also impact the context. Research has shown that in most stages of childhood, children exhibit some degree of sexual curiosity but adolescents as a group exhibit much more sexually motivated exploration than children (Murrie 2012).

However, there are children and adolescents who exhibit deviant sexual interests and behaviors that fall outside of the socially accepted range of normality and if acted upon can constitute a criminal offense. The determination of what exceeds acceptable adolescent behavior is most clearly understood through the legal definitions of abuse and age requirements for consent in a given jurisdiction. In Canada, for example, the Canadian Criminal Code defines the age of consent to sexual activity as 16 (Canadian Criminal Code 1985). However, in cases where an individual is in a position of trust over the consenting adolescent, such as a coach, teacher, or employer, the age of consent increases to 18. Also, the age of consent is raised to 18 in cases where digital media depicts nudity or sexual activity of the adolescent. In the United States, state law governs variation in age of consent to engage in sexual behavior with another. Determinations are made on a state-by-state basis except when there is photographic or video recording of the behavior, in which case the federal law takes precedence and the age is a minimum of 18 years regardless of the state (Sexual Exploitation and Other Abuse of Children, 18 USC §2256, 1984 amended 1986).

OFFENDER CHARACTERISTICS

Similar to their adult counterparts, ASOs are a heterogeneous population and differ on many important dimensions, including age at first offense, gender, and social and developmental characteristics. The following are some findings from the literature that provide general demographics. Although preadolescent children are known to commit abusive sexual acts, the dynamics are typically different, less clearly sexually motivated, and less frequent. The following is focused on adolescent-aged youth.

Onset and average age of offending

During adolescence, concern about appearance and self-image typically increases, together with an increase in frequency of sexual fantasies and masturbation (Saleh and Vincent 2004). Exploratory relationships, which can be exploitive, often occur during middle adolescence (Saleh and Vincent 2004). By late adolescence, the development of secondary sexual physical characteristics concludes, and ideally, sexual behaviors and interests become less solipsistic (Saleh and Vincent 2004). Consequently, sexual behaviors should be assessed within a developmental context rather than in absolutes. Although, taken out of this context, a behavior might seem exploitive and even abusive, it might be consistent with the person's developmental stage and as such warrant less significant or intrusive correctional measures, if any.

The average age for onset of sexual offending is the early teens; varying between 13 and 16 years of age for males (Bumby et al. 1997; Shaw 1999; Zolondek et al. 2002; Vandiver 2006) and 11 and 15 years for females (Bumby et al. 1997; Vandiver 2006). Retrospective data from adult sex offenders indicate that paraphilias typically first develop as deviant fantasies around puberty, followed by deviant behaviors 2 to 3 years later. Without treatment, by the time the adolescent reaches early adulthood, patterns of sexually deviant behavior are typically established (Saleh and Vincent 2004). Although there is no dispute that sexual interests develop and are modified from puberty to adulthood, there is controversy about when or if the modifiability of sexual interests stops. John Money and others have argued that sexual interest is like sexual orientation and becomes immutable (Money 1986; Cantor 2012). Others have suggested there is no evidence that sexual interest and behaviors are not continually and naturally modifiable throughout the life span (Fedoroff 2016).

Despite variation in the onset of sexual offending behavior, the age of first arrest for male and female adolescent sex offenders is similar. On average, adolescent females are first arrested at age 14 and males are first arrested at age 15 years. Age and risk of recidivism in adolescent sex offenders is inversely related (Vandiver 2006). That is, the younger the offenders are at the time of first arrest for a sexual offense, the more likely they are to be re-arrested for a nonsexual or sexual offense (Vandiver 2006). One explanation for this finding is that adolescents who begin offending earlier often also have more criminogenic factors and/or a lifestyle conducive to criminality compared to those who begin offending later in adolescence. For example, Seto and Lalumière (2010) did not find a significant difference between the age of first arrest for sexually offending adolescents and adolescents with nonsexual offending histories.

Table 46.1 Chapter definitions

Term	Definition
Adolescent	A person between the ages of 12 and 17 years inclusive, regardless of degree of physical or psychological maturity.
Child molester	A person who commits a sexual offense against a child. It is important to understand that not all individuals who have a sexual interest in children act on these interests and become child molesters. Some individuals suffer from deviant sexual fantasies or urges but never act on their interests. Conversely, not all child molesters have a persistent sexual interest in children, nor would they meet *DSM* or *International Classification of Diseases* (*ICD*) diagnostic criteria for pedophilia or pedophilic disorder.
Deviant sexual interest	The concept of being "deviant" is a statistical term referring to a quantifiable variable that diverges from an average score. Sexual interests are said to be deviant when they are outside the "norm" of a given population. This includes adults, adolescents, or children who have a sexual interest that is not in line with social prescriptions and, in some cases, legal definitions. Research on sexual offenders and those with problematic sexual interests are defined according to the laws and social norms of the jurisdiction and time period in which the research takes place. Regarding children and adolescents, little objective information regarding normal sexual development and exploration exists. Significant variation exists in what is considered "normal" child sexual exploration. It is unfortunate that the term "deviant" has become a derogatory label and is often falsely equated with immutability. By analogy, both people with genius and people with intellectual disability are deviant.
Juvenile sexual offenders (JSOs) or Adolescent sexual offenders (ASOs)	Refers to youth between ages 12 and 18 years who meet either of these criteria: (a) officially charged with a sexual crime or (b) committed an act that could be subject to legal charges. A juvenile is a person who is under an age fixed by jurisdictional law at which the person would otherwise have been charged as an adult. Some jurisdictions have an earlier cutoff period with adult charges being made once an individual turns 16 or 17. When convicted of a sexual offense, adolescents are subject to penalties less severe than if charged and convicted as an adult. There is also frequently an increased focus on rehabilitation over punishment. It should be noted that although the abbreviation ASOs is used in this chapter, in practice it is better to refer to "adolescents who have sexually offended" rather than the label ASO that implies being an offender is a permanent identity rather than a description of a past behavior.
Paraphilic disorders	Derived from the Greek "para" meaning around or beside and "philos" meaning love. Paraphilias involve arousal from sexual stimuli or acts that are outside the standard range of socially acceptable behaviors. However, for the individual with the paraphilia, this interest or behavior is persistent, often preferred, and in some cases necessary for sexual excitement and orgasm. Paraphilic disorders exist on a continuum from less conventional behavior to violent, harmful, or destructive behavior. Paraphilias are persistent sexually arousing fantasies, interests, or behaviors that involve nonhuman objects, suffering or humiliation of oneself or partner, or children or other nonconsenting people. To be considered a disorder, they must cause distress or harm to someone. Paraphilic disorders themselves are not illegal; however, acting in response to paraphilic urges may be illegal (sex offense), and in some cases, it could result in severe legal sanctions as is frequently observed in the case of pedophilic disorder. Patients with paraphilic disorders usually come to medical or legal attention by committing an act against a child or a nonconsenting adult because most of them, especially adolescents, do not find their sexual fantasies distressing or sufficiently ego-dystonic to voluntarily seek treatment. In addition, they may feel too ashamed to ask for medical advice prior to acting on their sexual interests. For some individuals, paraphilic fantasies or stimuli are obligatory for erotic arousal and are always included in their sexual activity (exclusive paraphilic disorders). In other cases, the paraphilic preferences occur only episodically, whereas at other times, the person is able to function sexually without deviant stimuli or fantasies.

(*Continued*)

Table 46.1 (*Continued*) Chapter definitions

Term	Definition
Pedophilia	A paraphilia that consists of persistent sexual interest and fantasies involving prepubescent children. In *DSM-5* the person must be at least 16 years of age and must be at least 5 years older than the victim. However, for younger people no age is specified and clinical judgment must be used (i.e., sexual maturity of the child and age difference between the victim and the perpetrator).
Sexual offense or sex crime	Criminal laws prohibiting sexual assaults are enacted in order to protect the right to autonomy and personal determination of involvement in sexual activities. Particular definitions vary among jurisdictions; however, within Western societies, the prohibition of nonconsenting or coerced sexual activity remains the constant. Attempts to protect children from sexual victimization by adolescents and adults remain consistent throughout Western cultures

Social and developmental characteristics

Research indicates ASOs are more likely than nonoffending peers to have learning deficits and conduct disorders that contribute to difficulties in the school setting (Zgourides et al. 1997). One study of ASOs in Canada found that nearly half of adolescent sex offenders experienced difficulty with educational activities and self-awareness, and had limited sexual knowledge. In addition, two-thirds of ASOs have limited social skills, experience difficulty making friends, and are often socially rejected by peers (Gal and Hoge 1999). One explanation for why some ASOs sexually assault younger children is because ASOs who sexually offend against children report closer social ties to younger children than to same-age peers (Timms and Goreczny 2002).

These findings are replicated in other studies in which ASOs were found to share characteristics such as loneliness, lack of suitable sexual education, lack of empathy or remorse for their victims, and limited self-esteem. Furthermore, ASOs are more likely to come from dysfunctional families in which abuse, inadequate supervision, and limited social support are common (Lakey 1994; Prentky et al. 2000). Although the sexually offending youth had more general and heterosocial skills deficits, they were statistically more likely to experience social isolation than the nonsexual offending youth (Seto and Lalumière 2010). In their study comparing alleged ASOs and nonsexual violent offenders in Germany, Driemeyer and colleagues (2013) found the former group were less sexually experienced, were less confident in their relationship skills, had a lower rate of victimization, and had more sexual deviance.

As a group, ASOs often display limited impulse control, judgment, and problem-solving skills (Kahn and Chambers 1991). Dwyer and Jerrell (2011) found oppositional defiant disorder (ODD) and disruptive behavior disorder (DBD) to be prevalent diagnoses within their sample of ASOs. A significant number of these adolescents were identified especially as having difficulties in the school setting. More than half of ASOs behave disruptively at school, 39% have been diagnosed with a learning disability, and 30% are frequently absent from school (Kahn and Chambers 1991; Bourke and Donohue 1996). When examining antisocial behavior by gender, female sex offenders tend to exhibit significantly fewer characteristics of antisocial behavior than their male counterparts. Other characteristics of female sex offenders may include use of drugs and/or alcohol, and physical fights with peers (Prentky et al. 2000; Lowenstein 2006). Brown and Burton (2010) found alcohol use to be the most robust predictor of a higher rate of nonsexual violence in their study of 290 male youths. However, Seto and Lalumière (2010) found nonsexual offenders had more substance use problems than the sexual offending adolescents.

Like their adult counterparts, many ASOs describe "cognitive distortions" they use to legitimize deviant sexual interests and which contribute to the commission of sexual offenses (Timms and Goreczny 2002). These errors in thinking manifest when offenders adopt beliefs about ways to behave consistent with their deviant sexual interests. According to Goocher (1994), some offenders sexually victimize others in order to regain personal control that they believe was taken from them when they were victimized themselves. For others, the rationalization or denial of deviant behavior works to reinforce offense facilitating thought patterns.

As a group, ASOs do not suffer from serious mental health issues, with less than 3% meeting *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) criteria for a serious mental illness or a severe personality disorder (Madsen et al. 2006). However, in another sample, 42% of adolescent sex offenders were found to meet the criteria for Major Depression (Poortinga 2009). Seto and Lalumière (2010) reported a higher rate of anxiety and low self-esteem but not depression, psychosis, or suicidal ideations in ASOs compared to nonsexual adolescent offenders. Dwyer and Jerrell (2011) examined the prevalence of mental health issues among juveniles with a history of sexual offending who were receiving treatment in a state mental health system. Based on the then current *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (*DSM-IV-TR*), the following diagnoses were found to be the most prevalent: attention deficit/hyperactivity disorder, oppositional defiant disorder, disruptive behavior disorder, adjustment disorder, mixed emotions and conduct, posttraumatic stress disorder, physical and sexual abuse

of a child-victim, and parent–child relational problem. In another sample, youth who sexually offended were found to have higher anxiety ratings than the comparison group. However, the authors cautioned that these data were collected after arrest (Fanniff and Kimonis 2014).

Some themes have been noted when examining intellectually disabled ASOs. As a group these individuals have been found to be more susceptible to the social influences of their peer group, especially if they live together. Their offenses have been described as more "opportunistic" (Timms and Goreczny 2002). Others have explained these observations as "counterfeit deviance" due to observer's misinterpretations of the true motivations for the behaviors (Hingsburger 1991). For example, a person raised in a group home in which nudity was common may be falsely diagnosed with exhibitionism if the person's behavior in a new context is misunderstood as sexually motivated. A history of previous victimization is also more prevalent in this subgroup. Intellectually disabled offenders are also more likely to have victims who are in close physical proximity, tend to use less "grooming" behaviors, and often use comparatively unsophisticated strategies to commit offenses or to avoid being caught. They are also more likely to say there was a genuine reciprocated intimate relationship with the victim (i.e., to say they were in love) (Timms and Goreczny 2002).

Childhood victimization

A history of abuse among ASOs has been suggested to play a role in offending behavior. A history of personal sexual abuse is common in juveniles who sexually offend (Ryan et al. 1996; APA 1999; Myers 2001; Morris et al. 2002; Shaw 1999; Hunter et al. 2003; Salter et al. 2003; Seto and Lalumière 2010). Robertiello and Terry (2007) suggest that ASOs typically report a history of childhood victimization. Results for this sample indicated that up to 70% of ASOs had a history of childhood neglect, 60% reported physical abuse, and 50% reported a history of sexual abuse. Dwyer and Jerrell (2011) found mental health system records for their study sample indicated 51% of males and 100% of females had experienced sexual abuse. Additionally, 31% of males and 90% of females had been physically abused.

Interestingly, Fanniff and Kimonis (2014) found that physical and emotional abuse were *not* predictive after controlling for sexual abuse in their sample. Fanniff and Kimonis (2014) also reported a higher rate of sexual abuse among juveniles who sexually offended compared to those with delinquent, but nonsexual, behaviors. Brown and Burton (2010) found higher levels of trauma, including abuse and neglect, in youth who engaged in nonsexual and sexual violence than those who were only sexually violent. Seto and Lalumière (2010) also found a higher rate of physical (but not sexual) abuse victimization among the sexually offending than the nonsexual offending youths.

The observed rates of sex offenders who have been sexually victimized in their childhood have led to speculation that the experience of sexual abuse may make individuals more likely to sexually assault others when they reach adolescence or adulthood. This speculation should be interpreted with caution. It is important to note that despite evidence that some victims of child sexual abuse do go on to offend sexually in adolescence and adulthood, the majority of victims never go on to sexually offend later in life. For example, while there is evidence of a high prevalence of victimization, including sexual abuse, among female children, relatively few subsequently commit sex offenses.

As a group, ASOs with a history of personal abuse are also more likely to experience family instability, have parents with alcohol and/or substance abuse issues, have parents with limited education, and experience interparental violence (Kobayashi et al. 1995; Veneziano and Veneziano 2002; Van Wijk et al. 2006). It has been speculated that since less than one-third of ASOs reside with both birth parents, this may result in less support and supervision (Hunter and Figueredo 1999).

Notable differences have been observed in the abuse histories of male and female ASOs. Surveys have found that females tend to have their first experience of sexual victimization at a younger age than their male counterparts. Approximately 64% of female sex offenders were found to have been victimized before age 6, whereas 26% of males reported being victimized by that age. In addition, females also reported having a higher average number of molesters than did male offenders, 4.5 and 1.4, respectively (Vandiver and Teske 2006). Adolescent sex offenders have a significantly higher prevalence of childhood sexual victimization than nonoffending adolescents (Burton et al. 2002; Veneziano et al. 2004).

ARREST RATES AND SENTENCING PATTERNS

Child victims and their families are generally more reluctant to report sexual victimization when the offender is an adolescent compared to when an offender is an adult. Presumably, this is because the offender is so young and is usually known to the family (Davis and Leitenberg 1987). Consequently, this likely results in a misrepresentation of the true rate of sexual offending committed by adolescent offenders. Sexual acts may also be labeled as an act of sexual exploration or experimentation, rather than an offense requiring police involvement. Moreover, only a small minority of incidents that are actually reported to the police result in charges or a conviction (Davis and Leitenberg 1987).

When examining the cases that do result in a conviction, it is important to look at sentencing patterns by gender and the nature of the offense committed. Research conducted by Vandiver and Teske (2006) found that female adolescent sex offenders receive a sentence involving probation in approximately three-quarters of cases, with the remaining cases concluding in sentences involving residential treatment. Generally, noncustodial sentences for male and female adolescent sex offenders tend to be similar. One survey

found that 77% of male adolescent sex offenders received a sentence of probation, and 22% were sentenced to "residential treatment" (Vandiver and Teske 2006).

However, the average sentence length of those in residential treatment was 2.8 years. Among those sent to residential treatment, 83% were given sentences less than 5 years, 12% were sentenced to 5–9 years, and only 5% received a sentence of 10 years or more. Differences emerge when comparing the average length of female sentences (2.8 years) to the average length of male sentences (5.5 years) (Vandiver and Teske 2006).

Only 50% of males received custodial sentences between 1 and 4 years, whereas 83% of females received an in-custody sentence of this length. Lengthier sentences of 10 years or more are given to males significantly more often than females, 27% and 5%, respectively (Vandiver and Teske 2006). It is possible that the coercive nature of some of the offenses committed by males may result in longer sentences than those of female offenders. Another possibility is that male sex offenders who receive residential sentences are viewed more harshly among judges than female sex offenders.

OFFENSE CHARACTERISTICS AND VICTIMIZATION PATTERNS

Early attempts to classify ASOs examined the contrast between offenders who strictly targeted children and those who offended against same-aged peers or adults. One study reviewed police records to identify characteristics that differentiated the two groups. Those with peer or adult victims were more likely than those with only child victims to have female victims (94% versus 68%) and to assault victims unrelated to the offender (84% versus 60%). This group also exhibited more gratuitous violence when committing the offense and showed higher rates of criminality in general (Hunter et al. 2000). This pattern is similar to adult sex offenders, in which those with pedophilia are less violent than nonpedophilic sex offenders (Motiuk and Brown 1996).

Victimization patterns have also been examined by comparing male and female ASOs. Although the majority of ASOs have victims who are younger than they are (Saunders and Awad 1988; Gilby et al. 1989; Greenfield 1997; Dwyer and Jerrell 2011), research generally suggests that female ASOs begin offending earlier than males. Females are also more likely than males to have younger victims ranging from infancy to 5 years of age (Veneziano and Veneziano 2002; Vandiver and Teske 2006). This may be due to their increased access to young children due to role-playing mother–child interactions as part of typical North American childhood play in which girls are given dolls and boys are given toy machines. In addition, male ASOs were significantly more likely to victimize someone of the opposite sex, whereas females tended to victimize both male and female victims equally (Fromuth and Conn 1997; Vandiver and Teske 2006).

RISK FACTORS

Similar to research on adult sex offenders, the literature on risk factors associated with ASOs focuses primarily on male offenders. One factor that increases the difficulty of accurate risk assessment in this population are the low recidivism base rates (Rich 2015), which range in the literature from 8% to 14% (Schram et al. 1991; Hagan et al. 1994; Rasmussen 1999; Miner 2002). The ongoing development and maturation of adolescents also need to be considered when examining risk factors in this population.

Traditional assessment of risk for sexual recidivism focuses on static factors that reflect past behaviors and experiences. Dynamic risk factors, however, involve variables that are amenable to change and are often used as treatment targets. How ingrained and persistent risk factors are in adolescent offenders is disputed. For example, Money claimed that "love maps" are established around age 8 and do not change, although unknown aspects of the love map may be discovered in later life (Money 1986). Cantor has claimed that pedophilia is "hardwired" due to a presumed abnormality of brain development and is therefore unchangeable (Cantor et al. 2008). Others have noted the fact that sexual interest changes in normal development (Fedoroff 2016). The literature on this crucial issue has been complicated by the conflation of variables such as gender identity and orientation with sexual interest and sex drive (Fedoroff 2016). It is generally agreed that some characteristics may be less resilient and more amenable to treatment than others, especially given the ongoing development of adolescents. Deviant sexual interest and psychopathic personality traits, for example, may be less static in adolescents than in their adult counterparts (Hunter 2012), and the *DSM-5* does not allow diagnosis of pedophilia in a person under age 16. As noted earlier, behavior and risk factors associated with ASOs must be examined through the lens of the social environment and in the context of child and adolescent development.

There are two general models of risk assessment with this population. The actuarial model involves statistical and mechanical assessment of risk based on comparison of static risk factors. Clinical risk assessment models are based on observation and professional judgment using defined risk factors. This model compares static and dynamic risk factors, while also taking into consideration protective factors (Rich 2015). Although each approach has its advantages, actuarial assessment has been found to be a more accurate predictor of risk overall, due to the fact that clinicians tend to "over-predict" recidivism (Hanson and Thornton 2000; Steadman et al. 2000; Harris and Rice 2007).

Research has identified some risk factors that are more strongly correlated to recidivism among ASOs. An empirical review of the literature by Worling and Långström (2003, 2006) identified five factors most strongly correlated with increased risk: deviant sexual arousal, previous sexual offense, multiple victims, social isolation, and failure to complete sex offender treatment programs. They also noted that problematic parent–child relationships and attitudes

supportive of sexually abusive behavior were possible predictors of risk, but were not as strongly correlated as the other five.

Self-reported sexual interest in children or in sexual violence was found to be highly correlated with risk of sexual recidivism (Worling and Curwen 2000). Similarly, adolescent sexual recidivists were more likely to report sexual fantasies involving children or the use of force than adolescents who had not recidivated. Interestingly, despite the consistent use of Penile Plethysmography (PPG) as a measure of deviant sexual arousal for risk determinations in adult sex offenders (Hanson and Bussiere 1998; Murphy et al. 2015a,b), research has not found a strong correlation between PPG and risk of sexual recidivism among adolescent sex offenders (Gretton et al. 2001). PPG assessments are generally not recommended for ASOs due to the uncertain reliability of this measure in the population and the ethical issues involved in presenting individuals who are still developing with deviant sexual stimuli.

A number of offense-related characteristics are associated with increased risk of sexual recidivism. Research on both adult and adolescent sex offenders has found a significant correlation between sexual offense charges or convictions, prior to the index offense, and risk of sexual recidivism in the future (Hanson and Bussiere 1998). Additionally, the number of victims impacts an offender's propensity to commit more offenses. ASOs with two or more victims were more likely to go on to sexually re-offend than those with one victim (Langstrom 2002; Worling 2002). Most sexual offenses are committed by someone who is known to the victim; and this is true for ASOs as well (Myers 2001; Morris et al. 2002; Zolondek et al. 2002; Dwyer and Jerrell 2011). These offense-related factors are often noted in measures aimed at identifying risk in this population (Worling and Långström 2006).

Inability or lack of interest in developing close social ties with age-appropriate peers has also been associated with repeat sexual offending. ASOs with limited social skills were found to be three times more likely to sexually recidivate than ASOs with secure social ties and without other identified risk factors (Langstrom and Grann 2000). Inability to develop and maintain strong social relationships and general social isolation are factors that contribute to increased risk of offending in both adult and adolescent populations (Hanson 2000).

Research on effectiveness of sexual offender treatment programs suggests that integrating approaches to help build strong social and familial bonds, while also offering offender-specific interventions, increases the likelihood of successful reintegration (Worling and Curwen 2000). Conversely, individuals who fail to complete treatment or are unwilling to participate are statistically at an increased risk of sexual recidivism. A review of literature on the risk of recidivism in adult and adolescent populations identifies a positive treatment effect (Hanson et al. 2002; Worling and Långström 2006). For example, in the Hanson et al. (2002) meta-analysis, treated persons had a rate of 12.3% and untreated ones a rate of 16.8%.

Although not found as consistently, problematic parental relationships and attitudes supportive of offending have also been associated with increased risk of sexual recidivism. A moderate correlation with sexual recidivism has also been identified with perceived parental rejection. This in turn has also been associated with strength of parental bonds (Worling and Curwin 2000). Cognitive distortions and attitudes that blame the victim or minimize responsibility have been linked to increased risk of recidivism. Helmus et al. (2013) in their meta-analysis found a small but significant value in predicting recidivism for what they termed attitudes supporting sexual offending. Please see Risk Assessment below for further comments on this topic.

APPROACHES TO TREATMENT

Traditionally, treatment programs for adolescent sex offenders have been modeled after treatment programs created for adult sex offenders. However, research has not established whether or not such treatment approaches work for the adolescent sex offender population (Veneziano and Veneziano 2002). Recently, treatment programs for adolescents have been more frequently delivered within the community setting and have been tailored to suit the specific treatment needs of the adolescent population (Veneziano and Veneziano 2002).

Treatment approaches for adolescent sex offenders are often composed of various offense-specific and offense-related treatment targets. Such targets often include deviant sexual interests, poor parental attachment, cognitive distortion, pro-offending attitudes, and impulsivity (Hunter et al. 2004; Worling and Långström 2006). Adolescent sex offenders who receive cognitive-behavioral treatment that emphasizes family intervention have been shown to be significantly less likely to recidivate (Center for Sex Offender Management [CSOM] 2006). When the language style and avoidance goals used within an adult-oriented relapse prevention framework are altered to fit the needs of youth, results have shown promise (Murphy and Page 2000; Hunter and Longo 2004). Some suggest that the emphasis on incurability (inherent in relapse prevention approaches) is likely to negatively impact the offender's self-esteem, motivation, and confidence. By reframing this component, adolescents are able to make more positive life changes while in treatment (Hunter and Longo 2004).

Treatment for ASOs often includes group and individual sessions. Group treatment is advantageous as it increases efficacy and also facilitates the sharing of common experiences. However, it can be limiting if used as the sole treatment approach with sex offenders, as individual treatment targets may not be comprehensively explored within a group setting (Rich 2003; Worling 2004). Individual therapy can be used to address personal issues relating to the sex offending behavior and to promote the practical application of concepts learned in group sessions (CSOM 2006).

Pharmacological treatment approaches are also used among sex offender populations but are rarely utilized

without concurrent therapy sessions. Anti-androgen treatments work to reduce testosterone levels and decrease the offender's overall sex drive. Due to ethical issues this type of treatment tends to be used more with adult sex offenders than adolescent sex offenders (Prentky 1997). Conversely, treatment for adolescent sex offending frequently involves techniques that are not specific to the sexually offending behavior but are deemed important in preventing future sex offending. Treatment targets and behavioral training among adolescent sex offenders usually focus on social skills and development, anger control, and substance abuse counselling rather than the use of drug therapy (Ertl and McNamara 1997).

Treatment outcomes among this population vary depending on the specific treatment targets and the general delivery of the program. Findings indicate when sex offender management strategies include a rehabilitative focus, the outcomes have been significantly more promising (Cullen and Gendreau 2000; Aos et al. 2006). In their review of the empirically supported treatment models, Dwyer and Letourneau (2011) recommended a family focused approach that focuses on healthy development without stigma. They also suggested use of treatment plans customized to the individual and taking into consideration that adolescents are still developing.

Guidelines for the treatment of male adolescent sex offenders between the ages of 12 and 18 have recently been published by the World Federation of Societies of Biological Psychiatry (WFSBP) (Thibaut et al. 2015). These guidelines are based on a systematic review of the literature and include discussion of 13 studies involving cognitive behavior therapy (CBT) and three studies involving multisystemic therapy (MST). Pharmacologic treatments involving selective serotonergic reuptake inhibitors (SSRIs), naltrexone (an opioid antagonist), medroxyprogesterone acetate (MPA) and cyproterone acetate (CPA), which are anti-androgens, and leuprolide (a gonadotropin hormone analogue, GNRHa) are also reviewed. The review is correctly cautious about advocating for any specific treatment due to the methodologic limitations of the published research. It notes that the levels of evidence as defined by Soyka et al (2008) are not good. Nevertheless, the WFSBP presents a treatment algorithm that begins with a recommendation for motivational interviewing, MST, CBT, and "psycho-social–educational" interventions (evidence level C or D). These psychological treatments are recommended for all adolescents regardless of level of assessed risk. Adolescents engaging in sexual behaviors with "low or moderate levels of violence" are recommended to receive SSRIs at the same dosages used to treat obsessive–compulsive disorder (evidence level D) with the caution that SSRIs have been associated with suicidal ideation in adolescents. The algorithm recommends that adolescents assessed as "high risk of violent sexual offending" should be treated with anti-androgens of increasing dosages followed by GnRHa's (evidence level D).

In addition to the low evidence levels in support of the recommended treatments in the above algorithm, there are additional levels of concern about following the algorithm as presented. The first is that the recommended treatments are based on sexual behaviors independent of diagnosis. A patient with major depression is more likely to benefit from treatments that also target depression than a patient with the same risk level but no mood disorder. The second is that SSRIs in the doses recommended in the WFSBP algorithm are associated with pharmacologically induced inhibited orgasm. Individuals with paraphilic interests are more likely to resort to their paraphilic fantasies if they have inhibited orgasm, making the treatment counterproductive. A third problem is the WFSBP focus on sex drive rather than paraphilic interest. For example, the WFSBP reviews and endorses treatment to reduce frequency of masturbation in adolescents who masturbate more than three times a day. There are many adolescents (and adults) who masturbate more frequently with absolutely no ill effects. Finally, the WFSBP recommends that antiandrogens be prescribed only by pediatric endocrinologists who likely have less experience with adolescent sex offenders than the average psychiatrist.

The WFSBP has attempted to provide some guidance for the assessment and treatment of adolescent sex offenders based on limited evidence. Some of the recommendations seem contradictory. For example, the WFSBP treatment guidelines for adolescent sexual offenders with paraphilic disorders state "we are unable to treat paraphilic disorders or sexual deviant (sic) behaviour specifically" (p. 21). Fortunately, the best evidence indicates that adolescents do well regardless of the specific treatment offered (Hanson et al. 2002; Reitzel and Carbonell 2006). According to the WFSBP article, only 15% of adolescent sex offenders are known to reoffend as adults (Worling and Långström 2006; Worling et al. 2010; Worling and Langton 2015). The most parsimonious explanation for this observation is that adolescent sex offenders recover from the factors that contributed to the index offence(s). We therefore recommend treatment be tailored to the individual needs of the adolescent, with algorithms being followed with extreme caution, if at all. For example, the WFSBP incorrectly states "pharmacotherapy cannot be a first-line treatment" (p. 27). The WFSBP correctly notes that motivation and willingness to follow treatment recommendations are important factors contributing to treatment efficacy. However, it also states, without reference, "In general, adjudicated youths are more motivated for treatment." In our experience, the reverse is true. This is because the aim of effective treatment is to enhance satisfaction from fully consensual sex. Treatment offered within adjudicated parameters is difficult to present as respectful of consensuality. Adolescents are quick to pick up on hypocrisy.

We recommend adolescent sex offenders be treated primarily as adolescents and with the expectation that they will develop consensual sexual interests. They should be told so, repeatedly. They should be educated about sex and especially that their problems are not due to sex itself, but rather due to sexual interest in nonconsensual themes (some paraphilias) and/or resorting to criminal acts. Efforts to facilitate healthy consensual sexual interests are almost always successful and easy to motivate.

RECIDIVISM RATES

A central theme in the literature on adolescent offenders is their propensity to re-offend and the likelihood that offending behavior will continue into adulthood. Studies on ASOs have found that rates of sexual recidivism tend to hover around 8%–14% (Schram et al. 1991; Hagan et al. 1994; Rasmussen 1999; Miner 2002). Studies examining the prevalence of nonsexual re-offending over an 8- to 10-year period reveal rates between 31% and 54% (Waite et al. 2005; Vandiver 2006). The most substantial point of this research is that a significant number of adolescent sex offenders continue to exhibit delinquent behavior and recidivate nonsexually, but relatively few continue patterns of sexual offending into adulthood.

Research by Sipe et al. (1998) followed a group of 164 juveniles convicted of a sexual offense for a period of up to 14 years after turning 18. At the time of the juvenile offense, the sample ranged from 11 to 18 years old. Results indicated that 10% of the juvenile sex offenders were arrested again in adulthood for a sexual offense and 33% recidivated with a nonsexual offense in adulthood. Interestingly, research has revealed that individuals with a high score on the Psychopathy Checklist: Youth Version (PCL: YV) and deviant sexual interests as measured by penile plethysmographic testing were more likely to recidivate sexually and nonsexually (Gretton 2001). Such findings suggest the presence of psychopathy in adolescent sex offenders may have much of the same implications from a criminal justice perspective as it does for adult sex offenders (Gretton 2001).

Risk factors that increase the likelihood an ASO will sexually re-offend include deviant sexual interests, prior criminal sanctions for hands-on sexual offenses, past criminal offenses with two or more victims, stranger victims, and social isolation from peers (Poortinga et al. 2009).

In order to understand the recidivism rates of ASOs in context, it is important to examine the relative recidivism rates of adult sex offenders. Bonta and Hanson (1995) performed a study on adult male offenders who were released from Correctional Services Canada between 1983 and 1984. The researchers examined recidivism within this group of males as measured by reconviction of any offense recorded. Findings indicated the base rate of sexual recidivism is significantly less than the general recidivism rate. For sexual offenders 10%–15% were reconvicted of another sexual offense over a 5-year period. When the follow-up period was extended to 10 years, the sexual recidivism rates increased to 20%. On a 15-year follow-up the rates rose to 25%.

The sexual recidivism rate in a group of mixed sex offenders was examined in a data set of 10 individual samples. Sexual recidivism was defined as new charges in the first five samples and by new convictions in the other five samples. The sexual recidivism rates for those who sexually assaulted adult women where similar to the rates of those who had sexually assaulted children (Webster et al. 1994). Although, it was found that rapists were much more likely than child molesters to re-offend in a nonsexual violent manner. Among the sample of child molesters, those who sexually offended against unrelated boy victims were most likely to sexually recidivate. This group was followed by those who offended against unrelated girl victims and by incest offenders (Hanson et al. 1993).

Although data support the fact that a large proportion of sexual offenders do not go on to sexually re-offend, it is important to note that many sex offenses go undetected by the police and official reports (Webster et al. 1994). According to Hanson et al. (1993), a reasonable estimate of actual rates of recidivism would be at least 10%–15% higher than the actual observed rates. As a result of these hidden figures of offending, it is difficult to accurately place the exact base rate of sexual recidivism. However, for the time being, such base rates are widely accepted and used in determining risk for sexual recidivism among adult sex offenders.

Concerning ASOs, two factors seem particularly important. The first is that risk of sexual recidivism decreases as age increases. The second is that risk of sexual re-offense decreases the longer the offender does not re-offend (Hanson et al. 2014). These two facts reinforce the likelihood that early interventions, especially if they precede commission of any crimes, are likely to be effective not only by preventing initial sex offenses but also by taking advantage of the fact that adolescents are developing and therefore, by definition, changing. It seems reasonable to expect successful interventions early on will pay off. Hopefully, ongoing research and treatment delivered with optimism about the outcome will show these statements are true.

SUMMARY KEY POINTS

- Almost half of sexual offenses are committed by adolescents
- Culture and context are factors of what is considered "normal" during early sexual exploration and development
- ASOs are a heterogeneous population and differ on many variables
- Although ASOs do not typically suffer from serious mental health issues, they are however more likely to have learning deficits, inadequate social skills, and conduct disorder
- Generally, families are more reluctant to report sexual offenses when the offender is an adolescent compared to if they were an adult
- Sentencing patterns for male and female ASOs are significantly different
- Treatment approaches often target offense-specific and offense-related treatment targets
- Treatment outcomes depend on the specific treatment targets set and on program delivery
- The risk of sexual recidivism decreases as age increases and the longer the offender does not reoffend

Juvenile competency to stand trial, competency attainment, and remediation

ERAKA BATH AND SHAWN SIDHU

INTRODUCTION

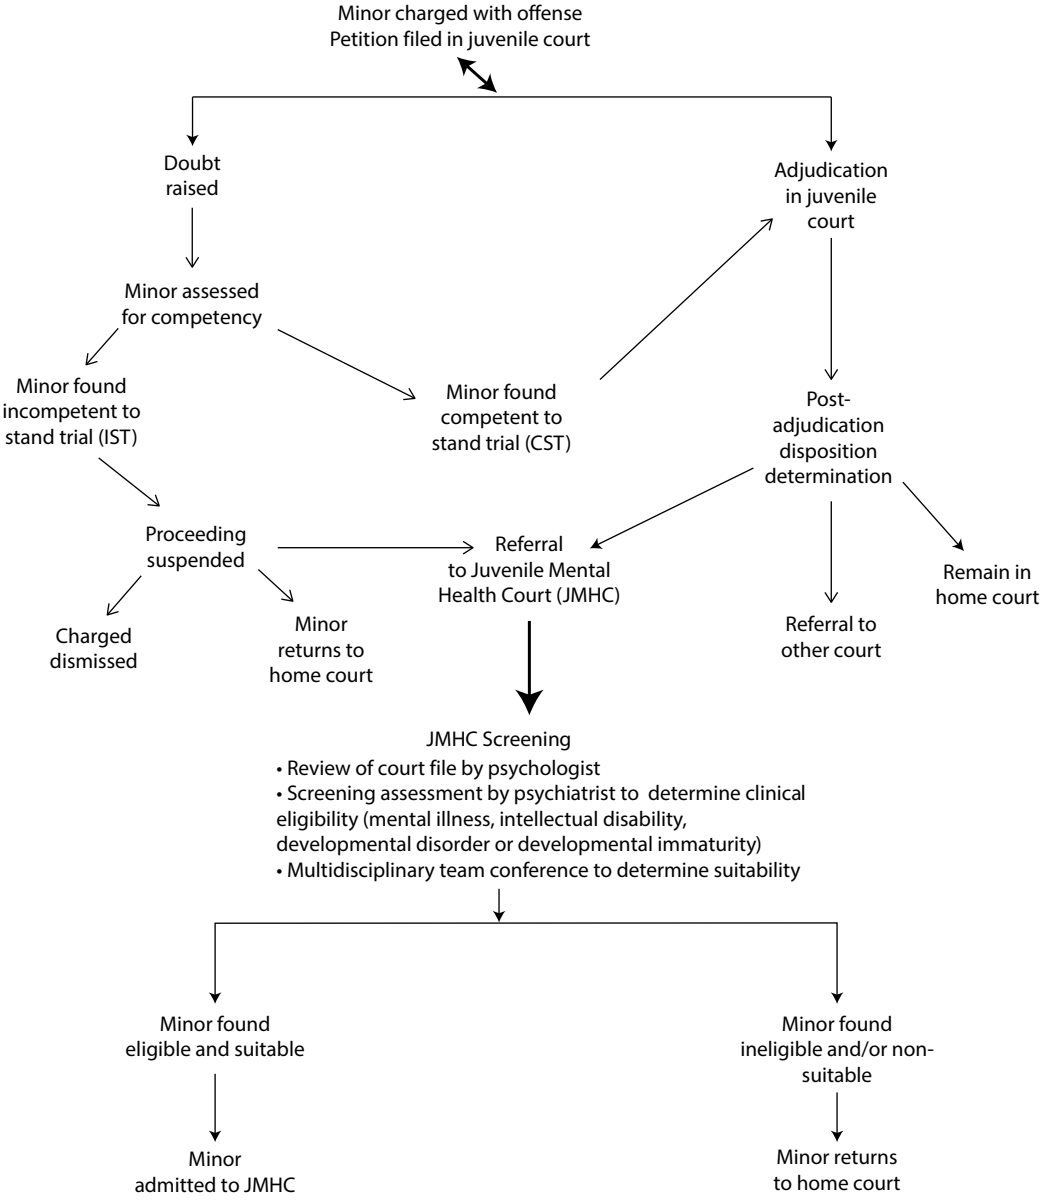
Legal competence is a critically important cornerstone of the U.S. legal system, a system rooted in the principle of equal justice for all, and which prides itself on providing numerous procedural safeguards to maintain fairness. Legal competence is a core component of the "Due Process" provisions that are constitutionally protected by the Fifth and Fourteenth Amendments (LII/Legal Information Institute 2014a,b). In *Dusky v. US,* the U.S. Supreme Court set forth the constitutionally required test for competence to stand trial (Baerger et al. 2003). Being competent to stand trial as defined by the *Dusky* standard requires that the defendant has (1) sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding and (2) a rational as well as factual understanding of the proceedings against him or her (Baerger et al. 2003). States vary in terms of including mental illness or developmental disability (or similarly worded predicates of competency) in their statutory definitions of competency to stand trial. In California, the *Dusky* standard is interpreted through Penal Code Section 1367, with incompetency to stand trial statutorily defined as being "a result of a mental disorder or developmental disability." In that sense, mental illness or developmental disability is considered necessary but not sufficient to be found incompetent to stand trial (IST). However, this statute does not mention the unique factors that arise in applying the competency issue to a juvenile population, namely, the impact of developmental maturity on competency to stand trial (CST).

Information about youths' competency to stand trial status is important for several reasons. First, states need guidance for the development of meaningful laws in this area. Basic research on cognitive and psychosocial development suggests that some youths will manifest deficits in legally relevant abilities similar to deficits seen in adults with mental disabilities, but for reasons of immaturity rather than mental disorders (Grisso et al. 2003). Unfortunately, nationally, the majority of states still do not have specific laws that address competency status in juveniles and default to the *Dusky* standard, a standard that was developed for adult defendants impaired by mental retardation and/or mental illness. Second, determination of a youth's competency to stand trial status may reveal important data about treatment and rehabilitative needs for highly vulnerable youth who may not otherwise be formally assessed or have had prior access to mental health treatment. For young offenders, all too often, psychiatric diagnoses, learning problems, and developmental and intellectual disabilities are first revealed *after* contact with law enforcement, and oftentimes during the course of a juvenile competency to stand trial evaluation. Nationally, many youth who come into contact with the juvenile justice system are racial and ethnic minorities.

JUVENILE OFFENDERS AND ADJUDICATIVE COMPETENCE

Once a youth enters the legal system, he or she is often placed in acute detainment until he or she receives a court date and can have a legal proceeding. Some youth may be on house arrest or other forms of holding during this time. If deemed competent to stand trial, the youth will then progress to trial and will undergo adjudication as determined by the judge. Common forms of adjudication in youth include a longer-term placement in a juvenile justice facility, placement on a forensic psychiatry unit or residential treatment center or home on probation, and possibly community service or another comparable punishment. Figure 47.1 provides a graphic illustration of a juvenile's pathway through juvenile court and where issues of competency may be raised.

The question of competence, in most states, may be raised by the judge, district attorney, or defense attorney (Grisso 2005a). Laws determine that these parties have an obligation to raise the question of competence whenever there is doubt that the defendant might have deficits in



Minor charged with offense
Petition filed in juvenile court
Doubt raised
Adjudication in juvenile court
Minor assessed for competency
Minor found incompetent to stand trial (IST)
Minor found competent to stand trial (CST)
Post-adjudication disposition determination
Proceeding suspended
Referral to Juvenile Mental Health Court (JMHC)
Remain in home court
Charged dismissed
Minor returns to home court
Referral to other court
JMHC Screening
• Review of court file by psychologist
• Screening assessment by psychiatrist to determine clinical eligibility (mental illness, intellectual disability, developmental disorder or developmental immaturity)
• Multidisciplinary team conference to determine suitability
Minor found eligible and suitable
Minor found ineligible and/or non-suitable
Minor admitted to JMHC
Minor returns to home court

Figure 47.1 Minor charged with offense petition filed in juvenile court.

abilities related to competence to stand trial (Grisso 2005b). The court then orders a competency evaluation by a psychiatrist or psychologist with training and experience in juvenile forensic work. In many states, the competency evaluation must be completed, and results reported to the court, within a specified time period, with the potential for requesting an extension of the time period under extraordinary circumstances. The examiner then prepares a written report of competence evaluation. If deemed incompetent, in accordance with the Fourteenth Amendment of the U.S. Constitution and *Dusky v. United States*, the youth cannot legally proceed to trial for adjudication.

It is important that forensic examiners be familiar with the legal criteria for juvenile competency to stand trial (JCST). Examiners must possess a unique blend of expertise, including special training, knowledge, skill, and experience (Grisso 1998). It is also important to be familiar with the justice systems they are practicing in and the typical youth that are involved with those systems (Kruh and Grisso 2008). Expertise should be focused on forensic assessment and child development. Specifically, child clinical and developmental expertise should be in the following: normal development, developmental psychopathology, and developmentally appropriate assessment (Kruh and Grisso 2008).

In communities where professionals with these credentials are not available, other professionals can receive certification to perform competency evaluations through continuing education courses. In the most rural areas of the country, experts can be called in to perform evaluations, or less preferably mental health professionals without training can perform the evaluation. In rural communities or small ethno-cultural communities, there is often only one

psychologist who is able to provide mental health services to a diverse-needs population (Fisher 2012). If a referral for competency to stand trial evaluation is made, and a forensic psychologist/psychiatrist is not available, any psychologist who has a background in clinical and/or assessment can conduct the evaluation. The Psychologists Code of Ethics Standard 2.01d (Standards of Competence) states that when psychologists are asked to provide services for which they have not obtained the competence necessary, psychologists who have closely related experience or prior training may provide such services if they make a reasonable effort to obtain the competence necessary by utilizing consultation, study, or relevant training and research. This standard provides two stipulations in which these services may be provided by a psychologist who does not have the education or experience required: (1) the psychologist's prior experience and training must be closely related to the service needed, and (2) agreeing to provide the service means that the psychologist must make reasonable efforts to obtain the skills and knowledge needed to effectively and efficiently conduct their work (Fisher 2012).

ASSESSMENT OF COMPETENCY TO STAND TRIAL IN JUVENILES AND REVIEW OF THE JCST SCALES

A variety of instruments have been developed to aid mental health professionals in the determination of competency to stand trial status. It is important to note that these instruments are only meant to be used as a supplement to a thorough clinical evaluation and do not definitively determine competency status independently. The majority of these instruments were developed originally for adults, and thus many were not standardized for use in children and adolescents. These tools vary in administration, structure, detail, objectivity of scoring criteria, empirical support, quality of concepts, domain detail, and generalizability (Mayzer et al. 2009). Examiners have the option to use standardized quantitative CST forensic assessment instruments (FAIs) or semistructured interviews that were developed specifically for use with the juvenile population (Juvenile Adjudicative Competence Interview, JACI) (Acklin 2012).

Juvenile adjudicative competence interview (JACI)

When a juvenile's competence is in question, the Juvenile Adjudicative Competence Interview (JACI) is considered the gold standard (Grisso 2005a). It provides the clinician with a structured set of questions to assess the understanding, appreciation, and reasoning in decisions about rights waiver as it pertains directly to the legal standard for competence to stand trial of the youth (Grisso 2005a; Kruh and Grisso 2008). Examiners are also provided with the definitions of the four dimensions of developmental maturity/immaturity and the various ways that these dimensions might present in an adolescent's responses to the JACI (Grisso 2005a; Kruh and Grisso 2008). The primary purpose of the JACI is to ensure that those conducting the examination are collecting relevant information to be considered when formulating an opinion about a youth's capacity for adjudicative competence (Kruh and Grisso 2008). All questions on the JACI should be presented to the youth in the order in which they appear on the form. At no time should the examiner rearrange the order or omit questions when administering the JACI.

The JACI is unique because if a youth fails to demonstrate an understanding, it provides a learning experience through "capacity checks." Capacity checks allow the examiner to teach the youth fact-related information pertaining to legal issues, and the opportunity to assess the youth's immediate and long-term retention of this information at a later time in the interview process.

Competence Assessment for Standing Trial for Defendants with Mental Retardation

The Competence Assessment for Standing Trial for Defendants with Mental Retardation (CAST-MR) is a highly structured interview including both multiple choice and open-ended questions designed to assess the competency of adult defendants who are intellectually disabled (Everington 1990; Kruh and Grisso 2008). The measure contains 50 items divided into three sections: Basic Legal Skills, Skills to Assist the Defense, and Understanding Case Events. These sections individually assess the defendant's knowledge of the adjudicative process, the defendant's understanding of the attorney–client relationship, and the defendant's ability to effectively discuss and communicate the facts of the case (Everington 1990; Kruh and Grisso 2008). Although the CAST-MR was not developed for juveniles, it was developed for defendants with limited cognitive abilities, and all items on the CAST-MR are set at a second-grade reading level, which makes it generalizable to youth (Kruh and Grisso 2008). The scoring criteria of this instrument are highly detailed and are provided for the open-ended questions; answers to the multiple choice questions are also provided (Kruh and Grisso 2008).

The CAST-MR is proven to have reliable scores, and demonstrate acceptable classification rates (Everington 1990; Kruh and Grisso 2008). However, it fails to assess for immature appreciation, which would require supplemental questioning. It also was not designed to assess psychosis-based threats to Competency to Stand Trial, which would eliminate it from being an appropriate choice if psychosis is of concern (Everington 1990; Kruh and Grisso 2008).

MacArthur Competence Assessment Tool—Criminal Adjudication

The MacArthur Competence Assessment Tool—Criminal Adjudication (MacCAT-CA) was developed by the MacArthur Foundation Research Network on Mental Health and the Law (Burnett et al. 2004; Acklin 2012). It is

a highly standardized 22-item, measure that generally takes approximately 30–45 minutes to administer, and is known as the "queen" of competency to stand trial instruments. It has three different sections that assess the Understanding, Appreciation, Decision Making, and Assisting through the use of vignette methodology (Burnett et al. 2004; Acklin 2012). A benefit of using vignettes is that it helps the clinician determine the quality of the response through the production of ratings: 2 (adequate), 1 (questionable), or 0 (inadequate). Another benefit of the vignette methodology is its ability to remove the youth's emotionality of his or her case to assess the youth's true abilities (Acklin 2012). The MacCAT-CA has demonstrated significant reliability, and internal consistency improving classification accuracy. There has been some criticism of the vignette methodology because it provides little opportunity to thoroughly assess the Appreciation and Understanding as it pertains to the defendant's case (Burnett et al. 2004; Kruh and Grisso 2008; Acklin 2012). This is a limitation of this instrument, and as a result, it is critical that the clinician also asks case-specific questions.

The MacCAT-CA was not structured with the intent of comprehension by juveniles (Kruh and Grisso 2008), but there are studies that have validated the use of the MacCAT-CA with the juvenile population. However, it fails to address issues pertaining to developmentally based issues of Appreciation, and therefore may raise a question into the appropriateness of its use with juveniles (Burnett et al. 2004; Kruh and Grisso 2008).

Fitness Interview Test-revised (fit-r)

The Fitness Interview Test-revised (FIT-R) is a 16-question, semistructured clinical interview developed for assessment of competency to stand trial with Canadian adult defendants, and was designed to match the Canadian standard of Competency to Stand Trial (Roesch et al. 2006; Kruh and Grisso 2008). It is grouped into three sections to assess (1) Understanding, (2) Appreciation, and (3) Communication, and consists of four background questions and 16 other interview items that are presented in a standardized manner. Interviewers are given the flexibility to perform the interview with more of a conversational flow compared to the much more structured instruments above.

This test was not normed with the youth population, but studies show that there is good interrater reliability and construct validity with the juvenile population (Roesch et al. 2006), strong interrater reliability on total score and scale, and weak interrater reliability on clinical ratings (Roesch et al. 2006; Kruh and Grisso 2008). Lower scores were obtained on the FIT-R for those with low verbal ability.

Descriptions with the meaning of each item are provided; however, scoring criteria are not. After each section has been scored, they are scored against a 0–2 scale that contributes to the qualification of Unfit, Fit, or Questionable (Kruh and Grisso 2008). The simple wording in the FIT-R makes it suitable for use with youth. However, it does not assess issues related to developmental maturity, or psychosocial developmental threats to decision making (Roesch et al. 2006; Kruh and Grisso 2008). As a result, when utilizing the FIT-R for assessment of CST with juveniles, it is important to include questions pertaining to these specific issues when asking case-specific questions. Table 47.1 summarizes competency assessment instruments.

RISK FACTORS FOR BEING FOUND INCOMPETENT TO STAND TRIAL

The understanding of the impact from mental disorders, developmental disabilities, and developmental immaturity on JCST has increased substantially over the past decade, particularly, given the unique nature of these impairments relative to adult defendants (Bath and Gerring 2014). Like adults, many juveniles possess significant cognitive and psychiatric impairments that may render them incompetent to stand trial (IST) (Burrell et al. 2008). Prevalence estimates of psychiatric illness in the juvenile justice population have been found to range from 66% to 75%, and estimates of youth who meet the criteria for a developmental disability or intellectual impairment range from 30% to 70% (Quinn et al. 2005).

When performing a competency evaluation in youth, it is important to keep a few key components in mind. There are several risk factors for incompetency that serve as a "red flag" for mental health professionals and legal officials when evaluating for JCST. Such risk factors include age, intelligence, presence of mental illness, presence of developmental disorder, and developmental immaturity.

Age

A study by McKee compared matched youths and adults referred for competency evaluations, and found that 40%–58% of youth compared to 11% of adults met criteria for intellectual disability or borderline intellectual functioning (Ficke et al. 2006). McKee (1998) found that compared to juvenile pretrial youth defendants, adults were significantly more likely to have higher mean competency scores than youth. Furthermore, the percentage of youth found competent dropped off steeply with age. For example, 15- to 16-year-olds were not significantly different from adults, with both groups yielding competency scores above 90%. Yet, those youth less than 12 years of age scored significantly lower at approximately 50% for the measure. In other words, the younger the patients were in this study, the more likely they were to be found incompetent to stand trial. This finding has been replicated in several studies (Cross et al. 1989; Marsteller et al. 1997; Bonnie and Grisso 2000; Ryba et al. 2003; Grisso 2005b; Larson and Grisso 2011), and thus lower age is considered to be a highly significant risk factor for being found incompetent. A considerable number of studies have examined the impact of age and cognitive abilities on juveniles' adjudicative competence abilities including assertion of rights to silence and legal counsel (Savitsky and Karras 1984; Abramovitch et al. 1995; Cowden and McKee 1995; Grisso 1997; McKee 1998; Goldstein et al. 2002; Baerger

Table 47.1 Table of competency instruments

Abbreviated name	JACI	FIT-R	MacCAT-CA	CAST-MR
Type of assessment	Semistructured interview	Semistructured interview	Quantitative instrument	Quantitative instrument
Normed for	Youth only	Adults, good reliability and vailidity in youth but does not assess maturity	Adults only	Adults, but generalizable to youth (second-grade reading level)
Assesses	Understanding, Appreciation, and Reasoning	Understanding, Appreciation, and Communication	Understanding, Appreciation, Decision Making, and Assisting	Basic Legal Skills, Skills to Assist the Defense, and Understanding Case Events
Unique Aspect(s)	Built-in "capacity checks" when youth fails a section where tester can teach the youth information and then later re-test this information to assess recall	Canadian Sections are scored as Unfit, Fit, or Questionable	Includes vignettes, which some argue is preferable to using the patient's own case information as it allows a more objective assessment	Includes Multiple Choice Questions for clients with verbal expressive difficulties
Strengths	Gold standard in youth Takes into account developmental maturity	Format allows more flexibility, but some argue there is too much flexibility	Potentially the most reliable and consistent instrument Good in psychosis	Gold standard in intellectual disability
Limitations	Cannot use in Adults Not quantitative No Multiple Choice	May not be the best in low verbal ability clients	Vignettes do not allow thorough assessment of Appreciation and Understanding	Does not assess for immature appreciation or psychosis

et al. 2003). The most comprehensive study of this type was the MacArthur Juvenile Adjudicative Competence Study (Grisso et al. 2003). They found that on the MacCAT-CA, youths aged 15 and younger performed more poorly on average than did young adults, with a greater proportion manifesting a level of impairment consistent with that of adults in past research that had been found incompetent to stand trial (Grisso et al. 2003). In addition, about one-third of youths aged 13 and younger manifested this significant level of impairment, while 16- to 17-year-olds on average were no different from adults in their performance (Grisso et al. 2003). This study highlighted the fact that age can serve as a risk factor for juvenile CST evaluation, which can guide forensic examiners on their assessment.

Cognitive functioning and learning problems

The second predicate factor for JCST is cognitive functioning. Several studies have documented that juveniles with lower intellectual functioning are more likely to have CST deficits. The literature on juvenile competency to stand trial dates back to the 1990s, when Cooper et al. studied juvenile detainees at a placement center (Baerger et al. 2003). They found that only Full Scale Intelligence Quotient (FSIQ) was significantly associated with youth who were ultimately found incompetent to stand trial, although a main effect was found for age. In most studies, with the exception of Burnett et al. (2004), intelligence estimates have been positively correlated and diagnoses of mental retardation have been negatively correlated with the performance of youth on all elements of broad competence assessment tools (Grisso et al. 2003; Ficke et al. 2006) and verbal abilities, but not some other cognitive skills (Viljoen and Roesch 2005). In a large-scale study by Grisso et al. (2003), the authors found that 40% of adolescents and young-adult participants with an IQ between 75 and 89 showed significant CST impairment. Furthermore, youth deemed incompetent to stand trial during CST evaluations tend to have lower intellectual functioning than competent youth (Evans 2003; Kruh et al. 2006), are more likely than competent youth to have diagnoses of borderline intellectual functioning and mental retardation (McKee and Shea 1999), and are more likely to be diagnosed with mental retardation than a mental illness (Baerger et al. 2003). Juveniles with seriously impaired intellectual abilities often have poorer understanding of the purposes, procedures, and participants in trials than juveniles the same age with better intellectual capacity (Grisso 2005a).

Another study by McKee et al. also found that a history of intellectual disability or borderline intellectual functioning was significantly correlated with an incompetent status (Grisso 2005b). Many studies have replicated this finding (Cross et al. 1989; Marsteller 1997; Bonnie and Grisso 2000; Ryba et al. 2003). However, as the literature began to progressively build on previous findings, the understanding of intellectual deficits in youth deemed incompetent became much more refined. The same study by McKee et al. demonstrated that 96% of detainees found incompetent had failed at least one grade in school (Grisso 2005b). Redlich et al. found that those who had poor overall grades and, more specifically, poor scores on vocabulary subscales were more likely to have a greater number of police contacts. They also found that those who had difficulty understanding their *Miranda* rights were also more likely to be deemed incompetent (Viljoen and Roesch 2005). A history of special education needs was significantly associated with an incompetent status in a study by Baergert et al. (Larson and Grisso 2011). Ficke et al. compared matched competent and incompetent youth in a study with lower IQ cutoff scores than previous studies, and found that an IQ less than 60 was highly predictive of being found incompetent (Ryba et al. 2003). They also found that lower Wide Range Achievement Test (WRAT) reading subscores correlated with a poorer performance on competency measures, such as the Mac-CAT. Kivisto et al. (2011) found that those with a higher score on the Wechsler Abbreviated Scale of Intelligence (WASI) were more likely to be competent (Cross et al. 1989), and data from Bath et al. (2015) suggest that those with a diagnosis of Intellectual Disability are more likely to be incompetent to stand trial (Marsteller et al. 1997). Thus, there is a substantial body of literature pointing to intellectual disability and a history of academic difficulties as legitimate risk factor for being found incompetent to stand trial.

Learning and academic functioning also seem to be associated with reduced adjudicative competence among juveniles, but results have been less consistent than with age and intelligence (Kruh and Grisso 2008). Some studies indicate that among juveniles referred for CST evaluations, it was generally found that youth found competent were less likely to have been in special education than incompetent juveniles (Cowden and McKee 1995; Baerger et al. 2003; Kruh et al. 2006; however, see McKee and Shea 1999, for a different result) but may be no less likely to be diagnosed with a learning disorder (Kruh et al. 2006). Although learning and academic functions are not as strong as predictors compared to those previously mentioned, it is something worth forensic examiners and legal authorities considering when adjudicating juvenile competence.

Mental illness

The third predicate factor for juvenile CST is mental illness, yet whereas there are significant data in the adult literature to support an association between mental illness and competency status, data on whether or not mental illness is a risk factor for incompetency in youth are mixed. McKee et al. found that 79% of youth referred for competency evaluations had utilized mental illness in the past (Grisso 2005b). Baerger et al. also found that prior mental health treatment was a risk factor for being found incompetent (Larson and Grisso 2011). Ficke et al. showed a correlation between younger detainees, externalizing symptoms on the Brief Psychiatric Rating Scale (BPRS), and lower Mac-CAT (competency) scores (Ryba et al. 2003). However, data from Grisso et al. suggest that Mac-CAT scores were unrelated to subject responses on the Massachusetts Youth Screening Instrument (MAYSI) mental health questionnaire (Bonnie and Grisso 2000). Kivisto et al. (2011) also showed minimal correlation between the MAYSI and competency status. Last, Bath et al. (2015) showed that those with an Axis I diagnosis of a mood, psychotic, or substance use disorder were in fact more likely to be found competent. Therefore, while data from some studies imply that mental illness is a risk factor for being found incompetent, other studies negate this finding.

Developmental maturity

The final predicate factor in CST is developmental immaturity. Developmental immaturity refers to specific deficits in neurological, intellectual, emotional, and psychological development. Intellectual development is another important aspect of developmental maturity in CST evaluations. Intellectual development in adolescence involves improvements in basic information processing skills, including organization of information, sustained attention, short- and long-term memory, and verbal fluency (Grisso 2005a). Gains in deductive reasoning and abstract thinking are important for participation in one's defense, which is an essential component in the adjudicative process (*Dusky v. U.S.* 1960). Two major areas of functioning highlight emotional development in adolescents: impulse control and emotional lability. This ability to delay responses in order to assess and consider consequences, and the quick changes in mood, can affect juvenile's decision making, making it more changeable and less stable (Grisso 2005a). Psychosocial development is important to consider because peer influences and negative risks of one's behaviors are approached differently in early and middle adolescence than in later adolescence and adulthood (Grisso 2005a). These psychosocial changes are important in regard to juveniles' participation in their trials and judgment in decision making. Psychosocial factors relevant to CST include the following: autonomy (conformity and compliance), perceptions, and attitudes about risk, temperance, and perspective taking (Kruh and Grisso 2008).

Research suggests that some youth will manifest deficits in legally relevant abilities for reasons of age alone (i.e., "developmental immaturity") rather than the presence of a mental or developmental disorder (Bonnie and Grisso 2000; Grisso et al. 2003). The often cited, large multisite study by Grisso et al. (2003), investigating correlates of CST in detained and nondetained participants aged 11–24, found

that approximately one-third of 11- to 13-year-olds and one-fifth of 14- to 15-year-olds were impaired in capacities relevant to adjudicative competence akin to seriously mentally ill adults who would likely be considered IST; those aged 16–17 did not differ significantly from young adults in terms of CST status (Grisso et al. 2003). More specifically, in a sample of detained youth, close to 35% of 11- to 13-year-olds and 22% of youth 14–15 years old were impaired in the areas of understanding and reasoning of trial-related matters, and youth aged 11–13 years old demonstrated less ability to focus on the long-term consequences of their decisions (Ficke et al. 2006; Larson and Grisso 2011).

Previous legal history

There is limited data present on the correlation between prior legal system involvement and competency status, and the data that exist are mixed. McKee et al. found prior arrests to be a significant risk factor for being found incompetent to stand trial (McKee and Shae 1999), while Grisso et al. found that performance on the Mac-CAT was unrelated to prior juvenile justice system involvement (Grisso et al. 2003).

NEUROBIOLOGY OF THE DEVELOPING ADOLESCENT BRAIN

Our understanding of the developing brain is growing every day. Adolescent brains when compared to those of adults show decreased dopamine activity in the prefrontal cortex and increased dopamine receptors in the ventral striatum, resulting in increased impulsivity and risk-taking behaviors (Steinberg 2008). Impaired decision making in teenagers has been linked to decreased impulse control, increased reward motivation, exaggerated emotional responsiveness, and increased susceptibility to peer pressure (Pope et al. 2012). These data are supported by Grisso et al., who found teenagers compared to adults significantly underestimated the risks of illegal activity as well as future consequences of short-term decision making (Grisso et al. 2003). As implied above, younger age correlated with poorer decision making in the context of police questioning and plea arguments as well in this study. Similarly, Kivisto et al. (2011) found that competency strongly correlated with the Judgment in Legal Contexts Instrument (JILC), and that future orientation helped to mediate the relationship between age, intellectual ability, and Mac-CAT scores.

RESTORING YOUTH TO COMPETENCY

There is ongoing debate about the best dispositional approaches for youth who have been found to be incompetent to stand trial. Whereas adult defendants can be remanded to a forensic hospital for competency restoration and treatment, juveniles are in a different category altogether. Because many jurisdictions lack forensic hospitals and competency restoration, remediation, or attainment programs for juveniles, there are limited dispositional options for youth who are determined to be incompetent to stand trial. The literature on juvenile competency restoration is sparse, and there are only a handful of programs nationally. Additionally, the nomenclature in describing juvenile competency restoration is in flux, with many experts differing in their opinion around the best terminology to use. Many argue that restoration is not an appropriate term, as many youth have never attained competency, so how can you restore what they never had? Emerging terminology suggests that Remediation and Attainment are the preferred terms growing in favor. For this chapter, the terms "attainment," "remediation," and "restoration" will be used interchangeably.

When thinking about juvenile competency attainment, it is important to consider the landmark case of *Jackson v. Indiana*. In *Jackson*, the U.S. Supreme Court held that a defendant could not be held longer than the reasonable period of time necessary to determine if there is a substantial probability that he or she would attain competency in the foreseeable future. This landmark case is guiding the efforts on juvenile competency attainment both in determining which youth should receive competency attainment services and the length of time those services should be provided. In some jurisdictions with limited competency attainment resources, youth who have lower-level misdemeanor offenses may be diverted out of the system if found incompetent to stand trial, whereas those with more serious, violent, or felony offenses may be selected to participate in remediation programs, given the public safety concerns.

Warren et al. (2010) has one of the few published papers in the area of competency restoration, and recommends that a good remediation program be an individualized and integrative community-based, developmentally and culturally appropriate program that is consistent with appropriate legal standards. Two of the primary goals of attainment services are to (1) assist the youth in attaining competency and proceed to trial, or (2) determine that the youth is not likely to be restored to competency in the foreseeable future and therefore divert from the juvenile justice system (Warren 2009). Warren (2009) created an interactive learning tool to assist with attainment of juveniles. This interactive learning tool is mental-health based and presents two adolescents, DJ and Alicia, who must appear in court. Warren's program uses a variety of techniques including role-playing, matching games, bingo, crossword puzzles, and videos within 24 chapters to address legal issues such as legal capacities, reasoning and decision making, perceived autonomy, perceptions of risk, time perspective, and abstract thinking. Participating youth receive these restoration sessions two to three times per week with trained Restoration Intensive Case Managers (RICM). The RICMs serve as the primary liaison between the court system and the youth and caregiver. The RICMs also function in a supportive capacity and help facilitate the adolescent's adherence to attending outpatient appointments. Results from this program have been promising overall; of the 563 youth found incompetent

to stand trial and ordered in the restoration program, 72% were found to be restored to competence within 90–120 days of remediation services. It should be noted that individual characteristics of the youth played a role in the restoration success rates, with the highest restoration rates occurring in youth without mental illness or intellectual disability (91%) and lowest restoration success in youth with intellectual disability (47%). These findings further underscore the importance of understanding clinical and demographics risks factors of incompetency, and how these may inform the ways in which attainment programs are provided to different groups, as well as correlate with restoration success rates.

FUTURE DIRECTIONS

The clinical relevance of juvenile adjudicative competency is multifold. We have already seen from some of the landmark cases in child psychiatry and the law, starting with *Roper v. Simmons* (2005), *Graham v. Florida* (2010), and recently with *Miller v. Alabama* (2012) that age matters (Bath et al. 2013). Adolescent brains are different than adult brains, and our evolving understanding of these differences demonstrates that there are behavioral correlates related to these neuroanatomical differences; these differences impact development, maturity, and decision making. These differences also result in adolescents being more likely to engage in impulsive and novelty-seeking behaviors without consideration of long-term consequences, and have an impact on their culpability as well as their legal capacities. Yet legislative and judicial responses to juvenile competency to stand trial have lagged behind the literature. Whereas the literature has consistently demonstrated over the last two decades that age is an important predicate of incompetency, most states do not have specific juvenile competency to stand trial legislation that recognizes developmental immaturity as a cause of incompetency (Bath and Gerring 2014).

SUMMARY

Although an emerging field within forensic psychiatry, juvenile competency to stand trial is an incredibly important and evolving area of mental health. Younger age, intellectual disability, and school difficulties have all consistently been shown to be risk factors for being found incompetent to stand trial, while the data on previous mental health and juvenile justice system remains mixed. An understanding of the complex needs of those youth referred for competency evaluation, and a deepening appreciation for the contributions of neuroscience have led to mental health professionals adopting a stance that favors treatment and rehabilitation. Mental health advocacy groups have had a significant influence on the legal system all the way up through the U.S. Supreme Court (Bath et al. 2013, 2015).

SUMMARY KEY POINTS

- Juvenile Competency to Stand Trial is a rapidly evolving, dynamic field in forensic psychiatry.
- A juvenile's right to be competent to stand trial relates to due process protections and the Fifth, Fourteenth, and Fourth amendments.
- The Juvenile Adjudicative Competency Interview (JACI) is considered the gold standard for competency assessment in juveniles.
- Juvenile competency assessment may reveal important data about a juvenile's psychosocial and learning needs. Risk factors for being found incompetent to stand trial include young age, the presence of intellectual and developmental disorders, and mental illness.
- Legislative changes in juvenile competency to stand trial have lagged behind the literature, which have long documented that developmental immaturity (young age) is increasingly being recognized as a predicate cause of incompetency.
- Mental health and legal professionals should be attuned to risk factors for incompetency, and when in doubt, refer defendants for competency evaluations if one or more risk factors are present.
- Juvenile competency restoration, remediation, and attainment remain an ongoing challenge and are the next frontier in the juvenile competency to stand trial debate.

Evaluating adolescent culpability

PETER ASH

INTRODUCTION

Criminal culpability, the degree to which a person can be held morally or legally responsible for a crime, is a necessary predicate for punishment. Forensic evaluations relevant to determining culpability may be used at many different stages of legal proceedings, including determinations of which charges a defendant will face, decisions about whether to waive a youth to adult criminal court, negotiations and plea bargaining, trials on the issue of guilt, and in sentencing and parole hearings. There is a range of defenses that involve culpability, from those that fully negate criminal responsibility, such as *mens rea* and insanity defenses, to those that reduce but do not negate responsibility. For adolescents, those defenses that negate responsibility are typically similar to those utilized by adults, whereas defenses that partially reduce responsibility are more common and differ significantly from evaluations of adults.

LEGAL BACKGROUND

Mens rea

Mens rea, or guilty mind, needs to be proved for a criminal conviction. Most commonly, *mens rea* can be inferred from the act itself, but in some cases, the defendant might argue that his or her actions were the result of an accident, self-defense, duress, or other reasons that would negate criminal intent. Some crimes include a specific intent in their definition: the difference between manslaughter and murder, for example, turns on a difference of intent (without malice afterthought, as opposed to with malice). In those states that allow for a diminished capacity defense, diminished capacity serves to reduce the culpability of specific intent, for example, to allow extreme emotional distress to negate premeditation and thus reduce a charge from murder to manslaughter. *Mens rea* defenses do not require that culpability be reduced by a mental illness.

Legal insanity

For those with a mental illness or mental defect, culpability may be negated by an insanity defense, which is available in all but a few states, but which varies in definition from jurisdiction to jurisdiction (AAPL Task Force 2014, S38–S76). The most common factors in insanity tests are that the act was connected to a mental illness and the defendant did not know (or appreciate) the act was wrong—the "cognitive test." Some states also have a version of a volitional test—that the defendant could not conform his or her conduct to the requirements of the law. There are other variations as well. For example, New Hampshire utilizes the "product of a mental illness" test. Insanity evaluations of adults are discussed more fully in Chapter 29 of this text.

Insanity pleas are far less common in cases involving adolescents than they are in adults, largely because psychotic disorders are less frequent in adolescents and because juvenile defendants who have a severe mental illness are less likely to be waived to adult criminal court. Only a small minority of states allow insanity pleas in juvenile court (Pollock 2001). Because one of the missions of juvenile court is rehabilitation, adolescents who suffer from a mental illness sufficient to substantiate an insanity plea typically have a treatment plan for their mental illness as part of their disposition. For adolescents tried in adult criminal court who would qualify for an insanity defense, the techniques and principles are similar to those used for adults (see Chapter 29 and AAPL Task Force 2014). A few adolescents may qualify for an insanity defense based on developmental delay or immaturity, such as an intellectually disabled early adolescent who does not know sexual exploration with a child is wrong, that may require the examiner to have expertise in interviewing intellectually disabled youth.

Reduced culpability of adolescents

In a series of U.S. Supreme Court cases since 2005, the court has found that minors—those under age 18—are less culpable

than adults. In *Roper v. Simmons* (2005), the court found "evolving standards of decency that mark the progress of a maturing society" had changed to the extent that the death penalty for youth under 18 years of age was "cruel and unusual punishment" and thus violated the Eighth Amendment and was unconstitutional. A large part of the court's rationale turned on three psychological aspects of adolescents: (1) that adolescents are developmentally immature, which included finding that they were more impulsive and more prone to respond to peer pressure; (2) that adolescent criminal behavior is often affected by adverse environmental circumstances over which they had no control (such as where they lived and the circumstances of their families); and (3) that their personalities are still in flux and so their actions could not be seen as reflecting enduring character traits. Five years later, in the case of *Graham v. Florida* (2010), using similar reasoning about adolescent culpability, and also noting that new neuroscience evidence about the development of the adolescent brain supported an understanding of why adolescents think differently from adults, the court held that a sentence of life without parole (LWOP) was unconstitutional for all nonhomicide offenses committed by minors. The *Graham* court also said, "A State is not required to guarantee eventual freedom to such an offender, but must impose a sentence that provides some meaningful opportunity for release based on demonstrated maturity and rehabilitation." This statement leaves unclear whether by "meaningful opportunity" the court was implying the state had a duty to foster rehabilitation, or whether the "meaningful opportunity" was a parole hearing at which the defendant had an opportunity to demonstrate he was rehabilitated. Two years later, in *Miller v. Alabama* (2012), the Supreme Court, again using the *Roper* analysis of adolescent culpability, ruled that even for murder, a *mandatory* LWOP sentence for adolescents was unconstitutional. The court did allow for an LWOP sentence following a murder conviction after a sentencing hearing during which the individual factors of a particular defendant and his crime were taken into consideration. By limiting the punishment options for adolescents convicted of serious crimes, the court opened the door to considering adolescent culpability issues both in future sentencing cases and in resentencing of adolescents who previously received sentences that would now be deemed unconstitutional. In the follow-up case of *Montgomery v. Louisiana* (2016), the Supreme Court clarified that *Miller* was retroactive, which means that all adolescents who previously received a mandatory LWOP sentence need either to have their sentence reduced to life with parole or to be resentenced under the *Miller* guidelines. Because adolescent culpability turns in large part on psychological factors, forensic evaluations of these defendants have an important part in sentencing hearings where life and LWOP sentences are being considered.

FACTORS TO CONSIDER

Taken together, the factors of various insanity tests and the issues highlighted by the Supreme Court in its adolescent sentencing cases provide a conceptual framework for assessing adolescent culpability. These factors are listed in Table 48.1.

In evaluations for an insanity defense, the evaluator needs to consider the factors pertaining to the relevant jurisdiction's formal test for insanity. If the adolescent meets the test for insanity, then he or she is fully excused from criminal culpability. Culpability lies along a continuum from fully excused to full responsibility. Most evaluations of adolescent culpability attempt to place the evaluated defendant on this continuum so other dispositional questions (such as appropriate punishment, trial setting, or disposition) can be appropriately answered. The Supreme Court holdings make clear that adolescents as a class are less culpable than adults, but it is far less clear how much reduction in culpability from adult standards is necessary to justify various dispositions. In evaluations for partial culpability, where the defendant does not meet the formal test for insanity, the factors utilized in insanity tests are nevertheless useful as areas to

Table 48.1 Factors to consider in evaluating adolescent culpability

- Factors pertaining to insanity defenses
  - Mental illness or mental defect
  - Appreciation of wrongfulness
  - Ability to conform to law
- Factors pertaining to reduced culpability
  - Immaturity
    - Impulsivity
    - Susceptibility to peer pressure
    - Risk taking
    - Time sense, overweighting immediate rewards compared to long-term costs
    - Limited ability to empathize
    - Incomplete brain development
    - IQ and adaptive functioning
  - Environmental circumstances
    - Adverse environmental factors, history of abuse and neglect
    - Peer group norms
  - Personality factors
    - Incomplete personality development
    - Psychopathy
    - Out-of-character action
- Nature of the crime
  - Degree of fit with patterns of adolescent crime as opposed to patterns of adult crime
  - Seriousness of the crime and harm done
  - Reactive attitudes toward the offense
- Other prognostic factors
  - Future dangerousness
  - Amenability to rehabilitation
- Malingering

examine to elucidate where on the continuum of culpability an adolescent defendant falls.

Mental illness

The rate of mental illness in juvenile offenders is very high (Marsteller et al. 1997; Teplin et al. 2002), about 60%, or about triple the rate in the general population, if conduct disorder is excluded. About 40% suffer from more than one disorder. Many delinquents meet criteria for conduct disorder, but because theft, lying, and serious violations of rules are considered symptoms of that disorder (American Psychiatric Association 2013), such a diagnosis is of little explanatory value. Although mental illness is common in this population, most studies of the causes of delinquency find mental illness to be a poor predictor of why a youth becomes delinquent (U.S. Department of Health and Human Services 2001; Grisso 2008). Mental disorder may well magnify the effects of other factors relevant to reducing culpability through such pathways as impairing judgment and increasing aggressiveness and impulsivity. There are some cases in which the offense appears to meet the "product of a mental illness" test that can serve to justify a finding of reduced culpability on the theory that mental illness reduces the ability to act freely and voluntarily. The presence of mental illness also has implications for rehabilitation.

Appreciation of wrongfulness

The M'Naghten rules, formulated by the British House of Lords in 1843, had as their central concept that the defendant was not culpable if he or she did not know what he or she was doing was wrong (M'Naghten's Case 1843). Variants of this concept are the most common prong in states' insanity laws. It is termed a "cognitive test" because it has to do with knowing. The most common situations meeting this test are that the defendant was psychotic and was acting either in accordance with a delusion (such as a paranoid person thinking he was acting in self-defense when no attack was in progress), or as a result of command hallucinations that would excuse the act (such as believing God was commanding the act). In some cases, not knowing the act was wrong might be a result of intellectual disability, as in the case of a severely intellectually disabled adolescent noncoercively molesting a younger child as a result of defects in social judgment. The evaluations of adolescents for an insanity defense generally follow the same principles as insanity evaluations of adults (see Chapter 29 and AAPL Task Force 2014), although experience in interviewing adolescents generally is helpful in using appropriate language and in forming rapport. Because the base rate of psychosis in adolescence is lower than in adults, and because psychotic youth are less able than adults to refuse treatment, evaluations of adolescents who meet the cognitive prong are uncommon. In most cases the offender knew his or her actions were wrong. A defendant either knew an action was wrong or did not; evaluations of partial culpability rarely focus on how wrong the defendant thought the act was.

Ability to conform to law

The insanity statutes of some states include a prong having to do with whether the defendant could conform his or her actions to the requirements of law, often termed a "volitional prong" because it has to do with free will. Evaluations of reduced culpability typically focus on factors discussed further below which reduce, but do not eliminate, an adolescent's ability to act lawfully.

Immaturity

A key issue in evaluation of partial culpability is the extent to which the adolescent's decision to engage in a crime was affected by developmental factors. Studies of adolescent decision making in contexts such as giving informed consent for health care, expressing preferences about custody when parents divorce, participating in decisions about educational planning, and making trial-related decisions (Lewis et al. 1977; Weithorn and Campbell 1982; Taylor et al. 1985; Garrison 1991; Grisso et al. 2003) are consistent in showing that adolescents 15 years old and older make decisions in these areas similar to adults. In those studies, which are all in contexts that allow time to reflect, about half of 13- and 14-year-olds had reasoning that was significantly worse than adults. These findings were used to argue for increased autonomy rights for adolescents over 14, especially in the context of arguing that adolescent girls over age 15 should be able to obtain an abortion without parental consent (American Psychological Association 1990).

The decision to commit a crime, however, is often made impulsively, and the Supreme Court in the series of cases beginning with *Roper* discussed above, has recognized adolescent impulsivity as one of the factors reducing culpability in adolescents. Impulsivity has a number of factors in addition to simply making a decision quickly. It has long been recognized that adolescents are much more susceptible to peer pressure than are adults. Unlike adults, who tend to commit crimes when alone, adolescents tend to offend in groups (Zimring 2005). Adolescents also tend to make riskier decisions than adults, and this tendency is increased when adolescents are in groups (Gardner and Steinberg 2005). These tendencies derive in part from the fact that adolescents tend to overweight immediate rewards when comparing them against long-term consequences. Finally adolescents show less empathy. All these interferences with judgment tend to improve through adolescence. Each of these factors can be assessed in evaluating an adolescent in terms of his or her maturity and in considering the circumstances of the crime itself (e.g., whether the crime was committed impulsively or after planning and whether the perpetrator was alone or in a group).

Recent research on adolescent brain development reveals structural changes in the brain through adolescence,

helping us understand the development of adolescent judgment (American Medical Association and American Academy of Child and Adolescent Psychiatry 2012; Luna et al. 2013; Casey and Caudle 2013). Speaking broadly, the limbic system, which is thought to contain critical structures related to emotion, develops earlier than the prefrontal cortex, which is the central area for executive processing. In addition, the nerve fibers connecting those two areas continue to myelinate over the course of adolescence and up to approximately age 25. Although neuroscience is not yet at the point of being able to use an individual brain scan to determine the culpability of an individual adolescent, brain research often is a compelling factor that helps judges and juries appreciate that adolescent impulsivity is not under full conscious control.

Adverse environmental circumstances

A number of adverse environmental circumstances, including child abuse and neglect, low socioeconomic status, and living in a high-crime neighborhood, are statistically linked to higher crime rates. Nevertheless, for adults, such factors do not generally mitigate culpability except in death penalty cases. The presumption of autonomy for adults holds that adults are expected to rise above such circumstances, in part because in theory they are able to distance themselves from them. Adolescents, in contrast, who find themselves in such conditions cannot independently escape from them. The Supreme Court has held that since such conditions are imposed, their effects reduce adolescent culpability. Evaluating the existence of such factors is relatively straightforward, although it is often difficult to demonstrate a clear link between the circumstances and the adolescent's behavior in a particular situation.

The strongest risk factor for adolescent violence is a delinquent peer group. In particular, gang membership is a main risk factor for adolescent violence. Because an adolescent chooses his peers, however, joining a gang is generally seen as a voluntary, not an imposed, circumstance, and gang membership is often cited as an aggravating factor. Nevertheless, in high crime areas, being tough is often protective, because being known as a pushover increases one's chance of being victimized (Garbarino 1999). One theory of morality holds that immoral action represents deviance from group values, so if a youth lives in a subculture that accepts and justifies violence when it is used to maintain respect on the street, an argument can be made that this reduces culpability in certain situations.

Personality factors

The third psychological factor the Supreme Court recognized was that an adolescent's personality is not fixed, and so an antisocial act committed by an adolescent does not represent a depraved character in the same way it would for an adult. Traits of personality disorder tend to diminish over the course of adolescence (Cohen et al. 2005). The most worrisome personality constellation is that of psychopathy, and even though psychopathy measured in adolescence has a significant correlation with psychopathy measured as an adult, the reported correlation is about 0.31 (Lynam et al. 2007), which is not high enough to be useful in making an accurate prediction in an individual case. Only about 20% of violent adolescents continue their violence into adulthood (U.S. Department of Health and Human Services 2001), and no predictors have been identified that allow for accurate identification of which adolescents will persist in their offending.

Ash (2012) points out some of the complications of the character theory of culpability. If a convicted defendant behaved out of character, federal sentencing guidelines allow for mitigation of punishment if the behavior "represents a marked deviation by the defendant from an otherwise law-abiding life" (U.S. Sentencing Commission 2003), although the guidelines specifically exclude mitigation for violent offenses on this basis. Such mitigation typically turns on the presence of some identified excuse, such as the defendant was intoxicated, under extreme emotional distress, or suffering from mental illness. Mitigation on the basis of out-of-character action seldom applies in adolescent cases, however. Studies of adolescent crime indicate the average adolescent at the time of arrest has committed numerous previous offenses, for most of which he was not caught (U.S. Department of Health and Human Services 2001). Prior to committing a first violent offense, self-report studies reveal that adolescent offenders have committed numerous and varied nonviolent offenses (Elliott 1994). Nevertheless, the possibility the offense is out of character needs to be investigated.

Nature of the crime

The extent to which the above factors are relevant to a particular crime often turn on the nature of the crime itself. In general, crimes committed by adolescents fall into a different pattern than crimes committed by adults. Some salient differences are shown in Table 48.2.

Adolescents are impulsive, and adolescent crime tends to be committed impulsively. However, in those cases in which a crime was planned in advance, the impulsivity of the adolescent perpetrator is not relevant. Similarly, most adolescent crime is committed in groups (Zimring 2005), so when an adolescent offends alone peer pressure

Table 48.2 Differences between juvenile and adult crime

Juvenile	Adult
More common	
Done in groups	Alone
Diverse offenses	Specialized
Impulsive	Planned
Criminal career shorter	

is seldom relevant. It is important to integrate factors that may reduce culpability with the hard facts about the nature of the crime.

Sentencing authorities commonly look to the seriousness of the crime and the harm done in their consideration of appropriate sentencing. An adolescent defendant's intent while committing the crime is highly relevant to his or her culpability, but crimes that "go bad" are punished more severely than the crime the defendant initially intended. Adolescent offenders are seldom practiced marksmen, and the difference between an aggravated assault and murder often turns on the chance path of the bullet rather than the intent of the shooter.

The reactive attitude a sentencing authority has toward adolescent crime also plays a large role. If one considers a situation from the perspective of "do the crime, do the time," one will have a very different view of appropriate sentencing than if one approaches the same situation from a perspective of "they're just kids" who need rehabilitation rather than punishment. Ash (2012) argues that much of the persuasiveness of explicating the above factors turns on their moving the fact finder to see the adolescent in terms different from an adult. Once one considers an adolescent as different, then the attitudes toward adult punishment are no longer in control, and it becomes necessary to formulate an alternative view of appropriate punishment. Society is still far from a consensus on what that view should be, but the trend is toward seeing adolescent crime as deserving of less punishment than adult crime.

Future dangerousness

Future dangerousness does not bear directly on culpability, but sentencing authorities are often interested in assessments of future dangerousness, because incapacitation is also a goal of punishment. Although adolescent crime is common, continuing an adolescent criminal career into adulthood is not. Only about 20% of violent adolescent offenders continue their violent careers into their twenties (U.S. Department of Health and Human Services 2001), and no robust predictors have been identified that allow us to identify which individuals will continue to offend.

Amenability to rehabilitation

Evaluations for juvenile courts often focus on a youthful offender's amenability to rehabilitation, in line with the rehabilitative mission of the juvenile court. In juvenile court, a focus on rehabilitation is often used to identify rehabilitative services. Amenability to rehabilitation is not, strictly speaking, an element that reduces culpability, although it is often a factor considered in sentencing and post-sentence rehabilitative services. In adult criminal court, the court's mission is typically not to foster rehabilitation. Nevertheless, as discussed above, the U.S. Supreme Court in *Graham,* where the court held unconstitutional life without parole sentences for youth convicted of crimes less than murder, noted that a youth must be given the opportunity to demonstrate rehabilitation.

Malingering

The possibility of malingering or unconscious distortion needs to be considered and explicitly addressed in the report when evaluating a criminal defendant, especially when examining the defendant's account of his or her role in the offense. In general, adolescents are less skilled at malingering than are adults.

THE EVALUATION

Many of the general principles of evaluations of criminal responsibility, including such issues as obtaining appropriate consent, interviewing techniques, and reviewing collateral data, are similar to those in evaluating adults covered in Chapter 29 and will not be repeated here. Evaluations of youth do, however, have some special characteristics.

Despite the fact that minors generally are not deemed competent, in most jurisdictions minors facing criminal charges are able to consent to evaluations that are court ordered or requested by their attorneys. Consent of parents or guardians is generally not needed, assuming the youth has legal representation. It is therefore especially important that the evaluator take care to make sure the youth understands the evaluator's role and other parameters of the evaluation. This may require education at the outset of the evaluation to foster the youth's understanding. Interviewing an adolescent is somewhat different from interviewing an adult, particularly in that language needs to be used which is appropriate to the defendant's developmental level. Because developmental information is important in assessing a youth's background environment and developmental level, school records, medical records, parent reports, and other collateral information are especially important in assessing youth. Police reports and other investigative material are crucial in understanding the nature of the crime, so it can be integrated with factors affecting culpability. Because issues of brain development play a strong role in assessments of adolescent culpability for serious crimes, neuropsychological testing to assess intelligence and executive functioning is often helpful, especially if testing can be conducted shortly after the offense, before the adolescent ages further in jail.

Integrating the findings

Many of the factors noted above lie on a continuum and do not have established metrics. For example, gauging a particular individual adolescent's impulsivity with respect to a particular crime requires integrating the defendant's developmental history, general level of maturity at the time of the offense, and impairments due to mental illness, with the actual circumstances of the crime. Although the general principles of the report are similar to other forensic reports on

criminal responsibility (see, for example, Chapter 29, AAPL Task Force 2014; Buchanan and Norko 2011), the relevance of developmental considerations usually requires a more complete discussion in order to educate the finder of fact as to why particular developmental considerations are relevant.

SUMMARY

Assessments of reduced culpability in adolescents challenge the evaluator to integrate a wide range of factors. U.S. Supreme Court holdings over the past decade have reduced the severity of punishments allowable for the most serious crimes committed by minors, and the court's underlying reasoning has found application to a wide variety of adolescent offenses. These principles are increasingly being used by defense attorneys to mitigate punishment for 18- and 19-year-olds, as well. As the legal landscape continues to evolve, evaluators of adolescent defendants increasingly have an opportunity to inform those who make decisions in these cases of a wide range of factors relevant to administering just punishment.

Forensic aspects of childhood bullying

BRADLEY W. FREEMAN

INTRODUCTION

Bullying, a new topic in this text, has been becoming more visible in the social landscape for children and adolescents in and out of school. This, of course, is not a new phenomenon, but the increasing media coverage and social climate change have brought bullying behavior into the limelight. There have been television shows, movies, video games, and numerous editorials that surround this topic either directly or indirectly. The government has established an anti-bullying website for the public, and the Centers for Disease Control and Prevention (CDC) have begun collecting statistics about the behavior. In March 2011, President Barack Obama and First Lady Michelle Obama hosted the inaugural White House Conference on Bullying Prevention that exemplifies the newfound interest and concern about this age-old social phenomenon (Shepherd 2011).

Following the Columbine High School massacre in Colorado on April 20, 1999, bullying became a frequent topic of discussion among students, teachers, parents, and politicians. This incident sparked discussions about gun control, social cliques, adolescent subculture, and violent video game exposure, among other topics. The publicized suicides of tormented students continued to fuel the movement toward finding an answer for bullying behavior. This public movement has culminated in evoking new legislation. Most states have both policy and legislation regarding bullying, but there remains no federal legislation directly focused on bullying.

The assessment of bullying (either victims or bullies) is complicated for several reasons. The behavior is often not readily apparent to authority, and the victims may not be open to assistance. Additionally, the evaluation of the victim encompasses different concerns than the examination of the bully. For instance, the bully evaluation could involve delinquency issues and almost always has a violence risk assessment as part of the overall examination. Victims, however, could be evaluated in the context of a civil suit, and this evaluation likely involves an opinion concerning diagnosis, damages, cause of the damages, and prognosis. Experts can also provide opinions about the psychological implications of bullying, including potential long-term effects and the interventions shown to be helpful in preventing bullying behavior.

Bullying behaviors can affect an individual into adulthood. For instance, victims can develop mood disorders and anxiety conditions. Additionally, bullying can influence the way in which people interact with others in the future. Falb et al. (2011) reported that after adjusting for age, race, and educational attainment, frequent victims of bullying had a higher risk of perpetrating intimate partner violence as adults. Meltzer et al. (2011) found that adults who reported being bullied in childhood were more than twice as likely as controls to attempt suicide later in life, even after controlling for other suicide risk factors.

WHAT IS BULLYING?

Bullying is a pervasive, widespread, cross-cultural, cross-gender phenomenon that appears to peak in early to mid-adolescence (Smith et al. 2002; Craig et al. 2009) and affects approximately half of school-aged youth worldwide (Wang et al. 2009; Mishna et al. 2010). Bullying has been defined in several different ways, but most authorities agree that there are three distinct factors that need be present to identify the behavior as "bullying." The first factor includes the presence of a power differential between the bully and the victim. The power differential does not necessarily need to be the classic physical disparity, but could be an intellectual, racial, or other difference. For instance, a minority student could be bullied by others due to their race without the bully having a physical advantage. The salient point is that the bully has some form of dominance over the victim. The second factor is that the bullying behavior is intentional. Furthermore, the intent is to intimidate, ostracize, demean, humiliate, or otherwise harm the victim in a substantial way. The final factor is that the bullying behavior is repetitious. The behavior is repeated until the bully achieves his or her goal, loses interest, changes the target, or there is an intervention by someone of authority (i.e., school resource officer, teacher, principal).

Bullying behavior can be categorized in four distinct areas (Table 49.1). The first category is physical bullying

Table 49.1 Bullying terminology

Bullying: A repetitive behavior over an extended period of time in which an individual with greater power attacks, humiliates, or intimidates a less powerful individual with malicious intent.

Physical bullying: When physical contact or a significant threat of physical contact is used to bully a less powerful individual (i.e., a student threatening to fight a less powerful student after school hours).

Verbal bullying: The deliberate use of language to cause psychological distress in another individual for the purposes of humiliation, intimidation, or other malicious reason (i.e., a student continually calls another student names in front of their peers).

Social bullying: When an individual uses his or her social status and/or interpersonal relationships to cause intentional and harmful distress in another individual (i.e., a student intentionally spreads hurtful rumors/gossip about another student).

Cyberbullying: The use of technology by a person to repeatedly and intentionally humiliate, embarrass, degrade, or otherwise harm a specific individual or group of individuals. There does not need to be a power differential present between the bully and the victim (i.e., a student regularly sends hurtful text messages/pictures to another student).

Sexting: Uses technology to send sexually explicit communication. This encompasses all forms of digital media (i.e., text, pictures, video). Sexting involves unwanted communication.

in which the bully uses physical intimidation to get their desired effect. The second type of bullying is verbal bullying. This occurs when adolescents use language to inflict harm onto their victims. In these cases, the harm is psychological and does not need to include physical injury. The third category is social or relational bullying in which the victim is indirectly attacked by the bully through maneuvers such as spreading rumors, ostracizing the victim from social groups, and other behaviors that cause emotional harm and/or social isolation. The last identified category is cyberbullying. Although these categories are distinct, bullies can use combinations of these behaviors to harm their target (i.e., name calling and physical aggression).

Cyberbullying is the newest arena for bullying and involves the use of technology. This form of bullying is unique when compared to the previous three "classic" categories. For instance, cyberbullying does not require the bully or the victim to ever meet in person, they can be separated by great distances, the power differential is much less important, and the bullying can be anonymous. Cyberbullying also continues to evolve as technology changes. The advent of social networking has played a significant role in the cyberbullying landscape.

Importantly, bullying is not constrained to a particular setting, although most bullies prefer an audience. Bullying can occur in all social settings, whether at school, at church, on the soccer field, in the library, or elsewhere. Of note, if the bullying occurs between an adult and a minor, it may very well qualify as child abuse. Additionally, the term "bullying" does not appear in all the different states' legislation or even in all school policies. The behavior is commonly referred to as harassment in many legal doctrines. In some suits brought against school systems, the plaintiff argued that the bullying behavior was essentially a form of harassment that violated his or her civil rights. Section 1983 of the Civil Rights Act is a popular avenue for plaintiffs to seek recourse when bullied in a public school setting.

EPIDEMIOLOGY

Like many social behaviors, bullying is likely underreported. In a national study from the CDC, 20.1% of high school students were bullied in 2011 in the 12 months preceding the survey; 22% for females and 18% for males. Additionally, 16.2% indicated they were bullied electronically; 22.1% of females and 10.8% of males (CDC 2012). The National Center for Educational Statistics determined that for the school year 2010–2011, 28% of students reported being bullied. Of those students, 65% were victims of relational bullying, and 63% were victims of verbal bullying. Approximately a quarter of those students were victims of physical bullying. With regard to cyberbullying, 9% of students reported being victimized in this way with the majority (50%) getting unwanted contact through text messaging (U.S. Department of Education 2011). In addition to victimization statistics, the bullies and bystanders have also been studied. Approximately 30% of young people admit to bullying others (Bradshaw et al. 2007). For bystanders, approximately 70% of students and staff have witnessed bullying. Interestingly, when bystanders intervene, the bullying stops within 10 seconds—a little more than half the time (Hawkins et al. 2001).

CYBERBULLYING

The newest form of victimization involves the use of technology. Cyberbullying has been given various definitions by various entities. The National Crime Victimization Survey defines cyberbullying as "having another student post hurtful information about the respondent on the Internet; make unwanted contact by threatening or insulting the respondent via e-mail, instant messaging, text messaging, or online gaming; purposefully exclude the respondent from an online community; or purposely sharing private information about the respondent on the Internet or mobile phones" (U.S. Department of Education 2011). This definition will continue to evolve with advances in personal technology

and social media. A 2014 review of state laws showed that 19 states have the term "cyberbullying" included in their policies and laws surrounding bullying, while 48 states describe electronic harassment. All states except Montana require schools to have a bullying/harassment policy in place (Hinduja and Patchin 2014). Physical bullying necessitates a face-to-face interaction, whereas cyberbullying requires the bully to utilize technology.

It has been reported that almost half of 12- to 17-year-olds viewed their online social network profile daily and 22% visited several times a day (Lenhart and Madden 2007). Other research has tried to determine how much time adolescents are spending using social networking sites. In a 2008 study, the youth surveyed spent an average of 33 minutes each day on social media, which subsequently increased to almost an hour the following year (Steinfield et al. 2008). It is estimated that 93% of adolescents are online, and of those, 39% are online frequently throughout the day. Being "online" covers many types of Internet access. Victims of cyberbullying have been targeted through various technological avenues such as social media, text messaging via smartphones, blogs run by other individuals, e-mail accounts, and online gaming. Schools have a difficult time policing cyberbullying because of the ease of access and due to jurisdictional restrictions. There has been debate about how far the school can reach outside the schoolyard and into the community with regard to its policies. This is evident in current state legislation that shows only 12 states have included off-campus behaviors as part of their policy.

Sexting is a relatively new phenomenon in which individuals will send others explicit communications through the use of technology. Sending adult-related material across the Internet is not new either; however, sexting typically refers to the use of mobile devices. Sexting is not constricted to text only. The advancement of technology has allowed individuals the ability to send any type of digitized media from one person to another. This, of course, includes audio, pictures, and video, which has permitted the distribution of sexually explicit material in all these forms.

Although sexting itself does not necessarily fall under the category of cyberbullying, this type of communication is often used to harass others. There are significant risks for adolescents who engage in sexting. Apart from issues of harassment, possession of indecent photos of minors could constitute a charge of possession of child pornography. In 2009, *Wired* magazine reported a 60-year-old veteran assistant principal was charged with such an offense. The assistant principal was charged with investigating sexting at the school and a boy he was questioning with the school resource officer sent a suspicious picture to the principal's cell phone. Although his defense was successful, the matter lasted a year and cost him $150,000 (Zetter 2009).

Adolescents are also not immune to prosecution. In 2013, the *Washington Post* reported on three high school students in Fairfax County, Virginia, who made cellphone videos of drunken sex acts with other teens and shared them among themselves. This behavior resulted in them facing charges of creating and distributing child pornography (Jouvenal 2013).

THE SCHOOL'S ROLE/RESPONSIBILITY

Whether public, private, or parochial, the school system enjoys a central role in many societies. The established common law doctrine of *in loco parentis* (Latin for "in the place of a parent") demands that the school be responsible for creating a safe environment for the students as well as for protecting their interests. The role of the school is becoming ever more scrutinized and increasingly important. State and federal legislatures continue to develop new policy and law to support equality and opportunity for students in our ever-changing social climate. The role of the school essentially establishes a *duty to care* for the safety of the student. Safety has become a pressing issue for schools in the post-Columbine era (i.e., after April 1999). It has been argued that the original *duty to care* has been superseded with a *duty to protect* (*Walton v. Alexander* 1997). Litigation against school systems and their officials is often due to this assumed duty.

The duty to care is embodied in either state law or from the Due Process Clause of the Fourteenth Amendment to the U.S. Constitution. This amendment protects citizens from state actions that result in loss of or injury to life, liberty, or property. Cases filed in federal court allege a constitutional violation of due process by the state (i.e., school officials) under Section 1983 of the Civil Rights Act. The Supreme Court ruling in *DeShaney v. Winnebago County Department of Social Services* indicated that when the state holds someone against his or her will, the Constitution demands that the state provide for the person's safety and well-being. Because of this ruling, some courts raised the level of responsibility of the school from *duty to care* to *duty to protect* because of the school's "functional custody" of the student (*Lichtler v. County of Orange* 1993). Still, most courts try to determine if a special relationship between the school and the student exists before raising the *duty to care* to the Constitutional *duty to protect*. Since the 1990s, courts have looked more closely at the elements of *imminent danger* to students and *deliberate indifference* by the school before imposing liability (*Walton v. Alexander* 1997). Under this lens, the plaintiff must prove the school intentionally ignored the behavior after being given notice or had knowledge of the injury risk.

In 1999, the Supreme Court determined in *Davis v. Monroe County Board of Education* that private actions could be levied against a school receiving federal funds in instances of harassment between students when it acts with "deliberate indifference" (*Davis v. Monroe County Board of Education* 1999). Justice Sandra Day O'Connor included in the majority opinion that the harassment must be so severe and pervasive that the educational opportunity for the victim is barred and the student harasser is under the

school's disciplinary authority. The ruling in the *Davis* case promoted the development of a five-part harassment test to determine the presence of public school liability based on Title IX of the Education Amendments of 1972. The five parts include that (1) the student is a member of a statutorily protected class (gender, race, disability); (2) the peer harassment is based on the protected class; (3) the harassment is severe, pervasive, and objectively offensive; (4) a school official with authority to address the harassment has actual knowledge of it; and (5) the school is deliberately indifferent to the harassment.

In the case of *T.K. and S.K. v. New York City Department of Education* (E.D.N.Y. April 2011), the federal district court found that a disabled student had a valid claim under the *Individuals with Disabilities Education Act* (IDEA) (*T.K. and S.K. v. New York City Department of Education* 2011). The student stated she was denied a free appropriate education due to bullying from peers because of her known disability. The court opined that a school should take quick and necessary steps to remedy bullying that interferes with a special education student's appropriate education.

The protection of free speech as elucidated in the First Amendment has been used by defendants charged with harassment. In the cyberbullying case of *Kara Kowalski v. Berkeley County Schools et al.*, a student sued the school for limiting her First Amendment right to free speech. The school suspended her after learning she had created a hate website directed toward another student at the school. The Fourth Circuit held that the speech created actual or foreseeable "substantial disorder and disruption" that the school was not required to tolerate and the student did not merit protection from the First Amendment (*Kowalski v. Berkley County Schools* 2011). In similar cases, *J.S. v. Blue Mountain School District* and *Layshock v. Hermitage School District* (*J.S. v. Blue Mountain School District* 2011), students were disciplined by the school for creating fake social media profiles of their principals. The parents sued citing the students' behavior was protected under the First Amendment right to free speech. In *Layshock*, a unanimous three-judge panel found in favor of the student holding that the offensive profile created by the student of the principal was protected free speech under the First Amendment (*Layshock v. Hermitage School District* 2010). In *J.S. v Blue Mountain School District*, a different Third Circuit panel of judges found, by a 2:1 vote, that the parody profile of the principal created by the student was not protected free speech. The basis of the opinion was due to the belief that the profile would lead to substantial disruption within the school. Both cases, although arriving at seemingly opposite judgments, relied on several Supreme Court cases including the 1969 case *Tinker v. Des Moines Independent Community School District*. The ruling in the *Tinker* case held that a school may not suppress a student's expression unless it will "materially and substantially disrupt the work and discipline of the school" *(Tinker v. Des Moines Independent Community School District* 1969).

STATE BULLYING LAWS

In 1999, Georgia was the first state to pass anti-bullying legislation. Since that time, all states, with the exception of Montana, have legislation that speaks to bullying behaviors. Montana has, however, adopted a statewide policy (U.S. Department of Health and Human Services 2010). The timing of bullying legislation appears to have begun, at least significantly, in the post-Columbine era. Many of the states that enacted legislation had model policies that provided guidance to state agencies. In 2010, the U.S. Department of Education (USDE) recommended guidelines for anti-bullying legislation in a report to Congress. The recommendations included 11 elements that are divided in four separate sections:

1. Purpose and definition (Components 1–4). Purpose, scope, definition of prohibited behavior, and enumeration of protected groups.
2. District policy development and review (Components 5–6). Implementation of policies, and review for compliance.
3. School District Policy Components (Component 7). Assignment of responsibility to carry out the law.
4. Additional Components (Components 8–11). Communication of policies, monitoring and accountability, actions and interventions to prevent bullying behaviors, legal remedies for victims.

Because these guidelines were introduced in 2010 and because each state is autonomous with regard to how they conceptualize legislation, there is little conformity among the states' laws and policies. Only two states, Maryland and New Jersey, have fully incorporated the USDE guidelines.

FEDERAL BULLYING POLICY

At this time, there is no federal legislation that directly addresses bullying. There are, however, federal laws that protect citizens against harassment based on sex, race, and national origin. In 2015, Robert P. Casey, Jr. (D-PA) introduced the Safe Schools Improvement Act (SSIA) of 2015 (S. 311 2015). This bill was designed to amend the Elementary and Secondary Education Act of 1965 to address and take action to prevent bullying and harassment of students. The updated bill has been referred to a committee for further consideration. In January 2015, the SSIA was reintroduced and sent to a committee. There are currently 40 sponsors who are overwhelmingly democratic.

The SSIA, if re-enacted, would demand that schools receiving federal funds establish a code of conduct that explicitly prohibits bullying and harassment. Schools would also be required to implement prevention strategies and professional development programs. The programs would need to help school personnel address bullying and harassment in a meaningful way. Last, the bill would require

individual states to collect data about incidents of bullying and submit that information to the USDE.

The bill addresses the disparities among the different states with regard to their bullying policies and legislation. With regard to cyberbullying, the bill includes "electronic communication" in its definition of bullying. The bill also denotes gay and lesbian students as a protected group as current federal law does not include sexual orientation as a protected group. Some people believe that the formation of this new protected group has been a barrier to the bill's passage.

ASSESSMENT

Forensic aspects

The forensic psychiatrist may become involved in cases of bullying or cyberbullying and may find himself or herself on either the left or right of the courtroom aisle. For plaintiffs, an expert may be hired to elucidate damages by way of determining a psychiatric diagnosis and/or associated constellation of symptoms that show the victim was damaged. Oftentimes, posttraumatic stress disorder, anxiety disorders, and mood disorders dominate the evaluations, for obvious reasons. Additionally, the connection between the youth's symptoms and functional impairments to the bullying behavior is a key concept, as the alleged bullying must be shown to have caused the damages. Without this link, the case has no merit.

The defense may also request the services of an expert to try and rebut the plaintiff's complaint of damages or scrutinize an opposing expert's opinion. Experts must remember to be blind to the party for which they are retained and remain as unbiased as possible in their evaluation. The court may also retain the expert. For instance, the court may ask the expert to evaluate the alleged bully, especially if the alleged bully has a history of delinquent behavior that has failed to improve despite previous court-ordered interventions. If the matter is being heard in juvenile court, the evaluator should provide a diagnostic assessment and treatment recommendations due to the rehabilitative focus of this venue. For youth evaluated in other courts, the expert may still provide a diagnostic assessment and treatment recommendations as part of the evaluation unless specifically instructed not to do so.

Oftentimes, the parties involved usually have a preferred outcome for the expert's assessment. This may be for the bully to escape punishment or for the victim to gain financial compensation or other resources. During the course of the evaluation, the expert must consider the potential bias of information provided and be vigilant with regard to malingering. Competent cross-examination will explore the weight placed on specific pieces of information that may, if not considered by the expert in formulating the opinion, confound the expert's conclusions.

Evaluations for the court are generally conducted with more rigor than what may occur in clinical practice. The opinions provided must be supported by data that are as objective and as valid as can be obtained. The assessments of victims and bullies are not identical as each has their own unique aspects. Before an assessment can begin, it is necessary that the expert understand several details about the referral. Most importantly, the expert must have a clear understanding of the referral question(s). It is often helpful to have the referring party send a letter detailing the particular question(s) that need to be addressed. It is fairly common for the referral source to have a limited understanding of an expert's services and how evaluations are undertaken. If the referral question(s) is unclear, the expert should certainly consult with the attorney or judge to better understand the issue at hand. The expert can also educate them about the possible areas in which the expert can, and cannot, provide an opinion. A clear and specific referral question will help guide the evaluation and provide a focused opinion. In addition to a clear referral, the expert will need other preliminary details such as the expected time frame for the report, if there are obvious conflicts of interest, payment for services, and other aspects that might influence the evaluation.

GENERAL ASSESSMENT OF VICTIMS AND BULLIES

Although the evaluation of the youth is not unlike a typical clinical evaluation, it contains aspects that are normally outside a clinical scope. The expert will need to inform the youth and their family that the report is not confidential and that it may be subject to public scrutiny. Additionally, they need to be made aware that a forensic evaluation is not for treatment purposes. The youth is then scheduled for an interview if he or she, and the family, agree to proceed.

During the interview, the youth is asked a comprehensive set of questions about his or her mental health and level of functioning in an age-appropriate manner. The expert may begin by asking the youth what the purpose of the evaluation is, what he or she has been told about the evaluation, if the expert was given "reminders" about what must be discussed or avoided, the youth's thoughts about the evaluation, and what the youth hopes the evaluation is going to accomplish. This type of questioning helps to assess for malingering, especially if the youth's responses seem scripted. Use open-ended questioning as much as possible as this approach provides the most reliable information (Oates and Shrimpton 1991). Begin by building rapport with the patient about neutral topics such as their family, their daily routine, and things they enjoy doing. As rapport develops and the interview continues, the questions become more focused on the issue(s) at hand. The evaluator may need to use more specific questions to complement the information obtained from the open-ended questioning approach.

The evaluation will need to explore psychosocial domains as well. Domains such as the youth's family life, school routine, peer socialization, and how the youth interacts

with their environment should be ascertained. Depending on the complexity of the history, the expert may find that creating a timeline of significant events is helpful. Parents, family members, teachers, coaches, and others can be useful sources of information with regard to the youth's psychosocial functionality. Persons who have known the youth before, during, and after the alleged bullying behavior are in an especially good position to compare and contrast behavioral and functional issues. Additionally, a full mental status exam must be conducted.

Psychological testing may be helpful. Testing should be based on the presenting problem or constellation of symptoms. The child's parents can complete mental health screening tools, and the youth can submit to testing for anxiety, mood symptoms, posttraumatic stress disorder, or other potential areas of concern. Additionally, some of the tools can be used to uncover dissimulation, specifically those containing validity scales. Two of the best predictors of malingering are internal consistency within the particular source and the external consistency with the other data collected. The child must also be assessed for safety. Necessary precautions should be taken if there is risk of harm to self or others.

In formulating opinions, the evaluator gives more weight to the data that are the most credible and unbiased. Not all forensic evaluations result in report writing. Unless a report is explicitly requested, the evaluator should consult with the referral source about the findings prior to engaging in writing a report. This has implications for the attorney involved as to what information may be discoverable. If diagnoses are identified, the evaluator must be able to support each diagnosis with data collected and include the rationale in the report. Support for each diagnosis must conform to the current established criteria.

The expert's opinions are essentially only as good as the information collected. Collateral sources of information play an important role in substantiating, elucidating, and weighing the data collected. With regard to bullying cases, collateral information is often provided from the parents/family, the school, treating providers, other individuals involved in the matter, and sometimes from police reports, surveillance video, medical and mental health records, and other official documentation. The amount of potential bias needs to be considered with each source of information and weighed accordingly. The weight given is usually based on the source's connection to those involved and what, if any, interest the source has in the outcome of the matter.

Persons outside the mental health field may attempt to equate "no diagnosis" with "no damages." Experts may need to explain that a psychiatric diagnosis is simply a label for a constellation of symptoms. Experts also need to explain that a person can still suffer significantly even though he or she may not meet the specific criteria for a major psychiatric disorder. For this reason, a focus on functional impairments is needed in addition to explaining the diagnosis or diagnoses provided. Also, the expert will need to describe the etiology of the symptoms as this relates directly to the legal idea of causation. Again, without a direct link between the bullying behavior and the damages, there is no causation and thus, no case.

Family and juvenile courts are interested in interventions that might be helpful for the youths involved. The evaluator will need to provide the court with specific treatment recommendations for the youth. Although this is not necessarily the case with criminal court, the expert may choose to provide recommendations there as well. Some experts believe that this blurs the line between a forensic duty and clinical care; however, courts are looking for guidance, and treatment recommendations can be helpful for the youth and the court's disposition of the matter.

Psychological testing and screening tools can be useful in a forensic assessment. The CDC has published a collection of assessment tools that address the evaluation of victims, bullies, and bystanders (Hamburger et al. 2011).

ASSESSING THE ALLEGED VICTIM

Evaluating the alleged victim includes screening for a wide variety of psychiatric ailments rather than performing a limited trauma assessment. The evaluator must collect a lifetime trauma inventory of the youth to better understand what may be producing or effecting current trauma-related symptoms. Because some children may be reluctant to discuss their past trauma, it may be necessary to rely on collateral information. The youth's bullying history is also a necessary area to explore. A bullying history helps to determine what type(s) of bullying the child has been exposed to and what the child's historical responses were to those experiences. The details about bullying incidents are similar to those of traumatic incidents. The youth should be asked about the nature of the bullying; why the youth believed he or she was targeted; and the duration, intensity, location, and outcome of the bullying behavior. The outcomes include the youth's change in thoughts, feelings, emotions, and behaviors related to the bullying he or she endured.

It is important to understand the victim's perception about how the bullying has affected his or her functionality. The expert can ask broad questions such as "What is different since the bullying? How has being bullied affected you? What is it like to be bullied the way you were bullied? Have you been bullied like this before?" The expert can then use the youth's responses to obtain more detailed information by asking more specific questions.

When interviewing the alleged victim's parents, it is important to gain an understanding of the child's behavioral and emotional history prior to and after the bullying. It is best to interview the parents individually and ask similar, if not the same, questions. By interviewing the parents in this way, the expert is better able to gauge external consistency of the other data. This can help to support or refute symptomatology and functional deficits that may be associated with the bullying behavior. The child's functional

Table 49.2 Examples of psychological tests to consider in the evaluation of bullying matters

Client type	Psychological tool
Victim and bully	Minnesota Multiphasic Personality Inventory-Adolescent (MMPI-A) Personality Assessment Inventory-Adolescent (PAI-A) Structured Clinical Interview for *DSM* Disorders (SCID) Child Behavior Checklist Trauma Symptom Inventory-2 (TSI-2)
Particular for victim	UCLA PTSD Reaction Index (RI) Child PTSD Symptom Scale (CPSS) Peer Relations Assessment Questionnaires-Revised (PRAQ-R)
Particular for bully	Structured Assessment of Violence Risk in Youth (SAVRY) Hare Psychopathy Checklist: Youth Version (PCL:YV) Level of Service/Case Management Inventory (YLS/CMI)

impairments need to be assessed in all domains, such as in their family relationships, academic performance, socialization with peers, behavior, spirituality, and employment. The evaluator must also assess pre- and post-event domains such as sleep, appetite, energy level, anxiety, mood, and somatic symptoms. A complete mental status evaluation is also completed.

Psychological testing can be useful in assessing the victim. Persons trained in testing should interpret the data and provide a summary of the results. Testing, although not infallible, can provide more objectivity as well as assess for dissimulation (Table 49.2).

ASSESSMENT OF THE BULLY

The difference between evaluating the victim and the bully essentially rests with the referral question. In most instances, the role of the forensic evaluation is to assess the mental and behavioral health of a juvenile suspected of bullying and offer intervention recommendations for the court. Additionally, the defense may be interested in looking for mitigating factors that might decrease the punishment or exculpate the youth altogether.

The evaluation of the youth suspected of bullying is generally in line with a typical clinical evaluation for mental illness with sensitivity surrounding secondary gain of avoiding punishment. As with the victim evaluations, the youth and the family should be aware of the lack of confidentiality surrounding the evaluation. They also need to understand the evaluation is not for treatment purposes. Collateral sources need to be obtained to help substantiate, elucidate, or refute information. Psychological testing can help provide objective data.

SPECIAL CIRCUMSTANCES

Evaluation of the school's response

The expert must be cautious not to stray into unfamiliar territory. An expert may be asked to provide an opinion concerning the response by the school system with regard to the bullying or harassment. In this instance, it is best left alone even if the school's response was obviously egregious or appropriate. Mental health experts would be wise to leave the evaluation of the school's response to others who are more familiar and have a better working knowledge of school administration and school policy. Unless the expert has specific training and experience in school administration, it is highly unlikely that a court would qualify the expert to be able to provide opinions in this area. The expert, however, may be able to comment on issues such as normal adolescent behavior, group contagion, and the social dynamics of a student body, but getting involved with the policy and procedures of a school system is not advised.

Postmortem evaluation

There are also disastrous occasions in which a youth will complete suicide due to bullying. In these cases, an evaluator may be asked to do a psychological autopsy to determine the motivation for the suicide. Evaluators who work in this area rely on various sources of collateral information to arrive at an opinion as to the etiology of the suicidal behavior. The evaluator must be sensitive to the surviving family members and the youth's community when conducting such an evaluation.

In postmortem evaluations, making a diagnosis is an academic task. In generating the opinion, the evaluator will need to search for connections between the decedent's behaviors surrounding the suicide with bullying behaviors of which he or she may have been exposed.

Video recording the interviews

There is some debate with regard to audio and video recording interviews with juveniles. As technology has progressed, creating high-quality recordings of forensic interviews is relatively inexpensive and easily facilitated. Still, there are other factors that need to be considered. Parents should consent to the recording of their child, and the youth must be made aware of the recording. Some practitioners choose to record all interviews whether it be with a child or an adult. Some prefer only to record under certain circumstances (i.e., want to preserve the youth's own words to be introduced in court). Video recording also allows the evaluator to capture body language, which can be very helpful when evaluating young children or individuals with limited verbal ability. If recordings are made, they need to be kept in a secure location as with all forensic records. Despite concerns of recording interviews, this can provide a great deal

of transparency, and it supports the notion that the report is objective and comprehensive.

Cyberbullying assessment and the use of a forensic computer investigator

Cyberbullying utilizes the newest frontier with regard to social interaction. This medium has the capacity to target victims without the bully having to be physically present. The bully can attack the target anonymously and can distribute the attack very quickly to a substantial number of people. Distribution of inflammatory or defaming material can easily be accomplished through the use of social media.

When assessing the victim of cyberbullying, the expert should follow a similar procedure as he or she would for a victim of other forms of bullying. With cyberbullying, the expert will also want to include a detailed history of the victim's computer use including the number of e-mail accounts the youth has, the youth's use of social networking, participation in online gaming, use of video communications, frequency of posting to online sites, and his or her online profiles. The expert may inquire as to the involvement of a computer forensic investigator who may be able to extract helpful data from the technology used in the bullying (Table 49.3).

SUMMARY

Bullying behavior is a social problem that will continue to exist in the world's societies. The behavior should not be tolerated due to the potential for severe outcomes to the victim and others involved. Schools deal with bullying behavior on a daily basis, and their response is encapsulated in their policies, procedures, and codes of conduct. Very few bullying incidents ever reach the level of legal intervention. Still, bullying-related lawsuits are on the rise. Mental health experts may find themselves presented with cases that involve all types of bullying behaviors. Experts must have a clear referral question in which to generate an opinion based on as much credible and unbiased information as possible. As with most forensic reports, the limitations of the evaluation should be discussed.

The history of correctional psychiatry in the United States

PETER N. BARBORIAK

INTRODUCTION

The number of incarcerated persons in the United States reached an all-time high in 2010. The U.S. Department of Justice estimated that federal, state, and municipal governments incarcerated a total of 2,279,100 individuals during 2010. The incarcerated population decreased by approximately 2.5% to 2,220,300 individuals by 2013. An additional 4,751,400 individuals received community supervision in 2013 (Glaze and Kaeble 2014). A significant proportion of these incarcerated individuals suffer from psychiatric disorders or substance abuse. In 2006 the U.S. Department of Justice estimated that over half of inmates suffered from mental problems and two-thirds of inmates had a substance abuse history at mid-year 2005 (James and Glaze 2006). Mental health services to mentally ill criminal offenders remain an urgent problem despite a long history of psychiatric service to prisoners (Metzner 1997a).

Correctional psychiatry refers to the practice of psychiatry in the correctional setting, including lock-ups, jails, detention centers, juvenile correctional institutions, prisons, and community corrections programs. Historically, correctional psychiatrists have engaged in treatment and rehabilitation of prisoners (Travin 1994). Prisoners with legally recognized emotional or mental disorders have been identified as mentally disordered offenders. Certain mentally disordered offenders, however, are not in the custody of a correctional institution (Halleck 1987; Wettstein 1998). This chapter focuses on the historical development of correctional psychiatry in the United States.

Much of the history of correctional psychiatry in the United States has been driven by a long-standing medical interest in explaining and treating criminal behavior. Social reformers, rather than physicians, played the most important roles in the origins of American correctional institutions. The beginnings of American penology and the invention of the prison arose from the same reform movements that gave rise to mental hospitals in the early nineteenth century. Historical developments that shaped psychiatric institutions exerted similar influences on the historical development of correctional institutions.

EVOLUTION OF THE PRISON

The modern system of correctional incarceration originated in the first half of the nineteenth century. Reformers in Great Britain and the American colonies sowed the seeds for this new system beginning in the eighteenth century. Georgian government authorities and moral reformers on both sides of the Atlantic sought to find a solution to the perceived problem of rampant lawlessness. Reformers attempted to find humane alternatives to the traditional punishments practiced in Great Britain and the American colonies, including branding, mutilation, flagellation, public ridicule, and death. Limited incarcerations in workhouses involving forced labor became a popular alternative to traditional punishments. In Great Britain, the existence of a large empire with areas ripe for settlement and forced labor suggested another solution. Beginning in the seventeenth century, but expanding significantly in the eighteenth century, British courts transported convicts to colonies in America, the Caribbean, and later, Australia. British reformers such as John Howard, and Quakers on both sides of the Atlantic, advocated a different approach. They suggested that criminals could be morally redeemed through reflection and repentance in a regularized, structured, and peaceful environment. They argued that penitentiaries would humanely redeem the fallen (McGowen 1995).

In a similar fashion Quakers and others advocated for and established asylums for the mentally ill beginning in the eighteenth century. They argued that "moral treatment" in asylums would humanely redeem the mentally ill. In addition, early nineteenth century mental health reformers were strongly motivated to provide adequate housing and treatment for the mentally ill, who were often confined in local jails in the absence of any other suitable place for

them (Grob 1994). Some historians have characterized the asylum and prison reform movements as merely flip sides of the same coin. Rothman viewed the emergence of psychiatric institutions and correctional institutions as part of an overarching mechanism to control social deviance in the United States (Rothman 1971).

The beginnings of correctional reforms in the United States are generally dated to 1790, with the opening of the Walnut Street Jail in Philadelphia, Pennsylvania. This facility pioneered the use of the "Pennsylvania system," which used solitary confinement as a tool to force the inmate to reflect upon and repent of his criminal behavior. The system was further refined at the Eastern State Penitentiary in Philadelphia, completed in 1829. Architects designed the physical layout of Eastern State Penitentiary as the "ideal prison," by meeting specific requirements of the Pennsylvania system, in which inmates were not allowed to interact with each other in any way. Proponents of the Pennsylvania system believed that total isolation would allow inmates to reflect on and reform their morals while protecting them from the corrupting influences of other criminals (Johnston 1994).

In 1817, New York opened Auburn State Prison and established the "Auburn system" model to secure and rehabilitate prisoners. In contrast to the Pennsylvania system, advocates of the Auburn system isolated inmates at night, but relied on group meals and hard labor performed in groups to provide the impetus to moral change. Inmates under the Auburn system were severely punished for talking to or otherwise interacting with each other. Although both models stressed isolation, strict obedience, and steady labor, fierce competition between advocates of the two systems developed by the 1830s (Friedman 1993).

Prison reform and mental health reform continued to be closely allied during the antebellum period. For example, Dorothea Dix, confident in the curative power of asylums, worked actively to reform jails and prisons. She tirelessly visited houses of correction, jails, and prisons, where she interacted with the prisoners. She took part in the controversy between the Pennsylvania and Auburn systems by writing in favor of the Pennsylvania system (Dix 1845, Gollaher 1995). Few American prisons during this period attempted to care specifically for mentally disordered offenders. The first psychiatric hospital for the criminally insane was opened next to Auburn State Prison in 1855. Eventually, hospitals for the criminally insane were opened in Massachusetts, Michigan, and Illinois (Halleck 1965).

Despite idealistic efforts to reform and humanize the criminal justice system, the new models themselves drew criticism as cruel and inhumane institutions. For example, Charles Dickens criticized the Pennsylvania system after visiting the Eastern State Penitentiary in 1842. He characterized the system as "rigid, strict, and hopeless solitary confinement." He witnessed inmates who suffered "an anguish so acute and so tremendous that all imagination of it must fall short of the reality." He wrote, "I hold this slow and daily tampering with the mysteries of the brain, to be immeasurably worse than any torture of the body" (Dickens 1842). Multiple criticisms of the early penitentiary systems reflected similar criticisms aimed at the asylum movement.

Prisons during the second half of the nineteenth century underwent a progressive decline in faith in the ability of the established prison models to redeem inmates. The period between approximately 1870 and 1900 witnessed the rise of a new correctional philosophy called the reformatory model. This model stressed the use of education and vocational training, combined with indeterminate sentencing, to promote change in the prisoner (Friedman 1993).

THE RISE AND FALL OF PSYCHIATRIC CRIMINOLOGY

Biological and anthropological theories dominated explanations for criminality and other antisocial behaviors in the nineteenth century. For example, the work of the Italian criminologist Lombroso postulated the existence of hereditary physical criminal types. Theorists on the etiology of crime, including psychiatrists, during the late nineteenth century supported the concept of a "criminal brain" based on anatomical and physiological studies. The practical application of such ideas led to the eugenics movement and sterilization of criminals in the early twentieth century (Halleck 1965). Subsequently, psychiatrists and others found little empirical support for hereditary biological and anthropological theories of criminal behavior. Noted psychiatrist William Alanson White effectively argued against coerced sterilization in 1915 (White 1917).

The origins of psychiatry's interest in developing an alternative to moralistic, biological, or anthropological theories of criminal behavior began in the nineteenth century. Interest in studying and treating antisocial and other deviant behaviors can be traced back to the father of psychiatry, Benjamin Rush. Rush suggested that medical causes could account for deviant behavior in his psychiatric textbook of 1812 (Rush 1812). This intellectual movement only began gaining momentum in the late nineteenth century. Correctional psychiatrist H.E. Allison called for psychiatric examination of all offenders as early as 1894 (Allison 1894).

The early twentieth century witnessed the flowering of the Progressive Era. Progressives believed in the rational reformation of society by experts. Though generally considered to date from approximately 1900–1920, the influence of the Progressive Era on correctional psychiatry extended from the 1920s to the 1960s. During this period, psychiatrists strove to view crime through a medical model and to establish a psychiatric criminology. Ultimately, optimism in psychiatry's ability to understand and treat deviant behavior scientifically led to calls for alternatives to incarceration and outpatient approaches to treatment.

The rise of a juvenile justice system during the Progressive Era played an important role in the development of correctional psychiatry. In 1909, William Healy established the first court clinic in Chicago, where he conducted psychiatric evaluations for the court. His model for a court clinic was

later copied in other juvenile courts, and in adult criminal courts in major jurisdictions. In conjunction with the young sciences of psychology and sociology, Healy fostered a psychiatric interest in the study of delinquency that laid the groundwork for the rise of a medical model of crime, and influenced studies of psychopathy and antisocial behavior (Healy 1915; Levine and Levine 1992).

Another source for the origins of psychiatric criminology came from the mental hygiene movement. Founded by Clifford Beers, a former patient, with support from psychiatrists and psychologists in 1909, the National Committee for Mental Hygiene aimed to protect the public's mental health. The mental hygiene movement advocated for preventive measures to curb delinquency and criminal behavior (Salmon 1920).

Caught up in the ideals of the Progressives during the 1920s, psychiatrists argued strongly that psychiatric expertise could solve the problems of criminals and crime. Excitement over new psychological insights provided by psychoanalysis also played a role in this movement, in which the state of Massachusetts played a pioneering role. In 1921, Massachusetts enacted the Briggs Law, which called for psychiatric examination of all defendants charged with a capital crime, or felons with prior felony convictions (Halleck 1965). Prominent psychiatrists such as William Alanson White, superintendent of St. Elizabeth's Hospital in Washington, DC, called for closer relationships among psychiatrists, attorneys, and the courts (White 1927). Prominent legal scholars such as Sheldon Glueck reflected the growing interest of progressive attorneys and judges by incorporating the latest psychiatric concepts in their work (S. Glueck 1925).

Psychiatric explanations for criminal behavior catapulted into the general public's attention during the sensational Leopold–Loeb trial, an early "crime of the century." Nathan Leopold and Richard Loeb, two 19-year-old sons of wealthy Chicago families, murdered a 14-year-old boy in 1924. Their attorney, Clarence Darrow, successfully used the psychodynamic expert testimony to avoid the death penalty. Defense experts included William Healy, William Alanson White, and Bernard Glueck, a psychiatrist at Sing Sing Prison in New York. Psychiatric aspects of the Leopold–Loeb trial further encouraged the development of psychiatric criminology (Diamond 1994).

Leading psychiatric reformers wished to apply the medical model to the correctional system. They criticized the traditional correctional approach of punishment as cruel and ineffective. They urged a scientific, individualized approach "which has rehabilitation and reconstruction as its end" (B. Glueck 1935). Despite the rhetoric suggesting a possible medical cure for crime, correctional psychiatrists engaged in little treatment. Psychiatrists working for the courts and correctional institutions concentrated on diagnostics and classification (Halleck 1965). The first survey of correctional psychiatrists conducted by Overholser in 1928 identified 29 correctional institutions with at least one full-time psychiatrist and 64 institutions with at least one part-time psychiatrist. Overholser found that 110 criminal courts out of a total of 1058 employed full- or part-time psychiatrists (Overholser 1928).

The Committee on the Legal Aspects of Psychiatry of the American Psychiatric Association played an important part in advocating for increasing psychiatric involvement in corrections and psychiatric criminology. Psychiatrists such as Karl A. Menninger and William Alanson White represented crime as a kind of failure in life adaptation that fell within the focus of psychiatry. They asserted that psychiatric study of individual criminals and their crimes would lead to "an efficient and scientific solution" to the problem of crime. The Committee on Legal Aspects of Psychiatry issued a report supporting these views in 1925 (Grob 1985).

The interest in developing a psychiatric criminology and applying that knowledge to the criminal justice system flourished in the 1930s. Leading psychiatrists, lawyers, and judges continued to foster the process of close cooperation. The beginning acceptance of psychoanalytic theories engendered a confidence in fledgling American psychoanalysts that they could unlock the unconscious and psychosexual origins of criminal behavior. American psychiatrists were strongly influenced by the translation and American publication in 1931 of the seminal German study of the psychodynamics of crime, *The Criminal, the Judge and the Public* (Alexander and Staub 1931). In 1931, the Forensic Psychiatry Committee of the American Psychiatric Association, including members William Alanson White, Bernard Glueck, and Winfred Overholser, proclaimed that psychiatry must play an important role in the problems of crime (American Psychiatric Association 1932).

During this period, psychiatric work with criminals earned prestige and respect from others in the field. The National Commission on Law Observance and Law Enforcement, in conjunction with the American Bar Association, recommended that larger courts routinely access psychiatric expertise by establishing court clinics (American Psychiatric Association 1931). The establishment of court clinics resulted in the routine evaluation and occasional treatment efforts toward defendants in major cities. The first psychiatric clinic attached to an adult court was founded in Detroit in 1919. Subsequent court clinics opened in Baltimore, Chicago, New York, Cleveland, Pittsburgh, and Philadelphia. The American Psychiatric Association formally recognized the growing importance of forensic and correctional psychiatry by organizing a Section on Forensic Psychiatry in 1934 with William Alanson White as its first chairman. This and similar developments led to "golden years of awakening in the field of criminal Jurisprudence" (Zilboorg 1944).

Psychiatric interest in the "sexual psychopath" developed in the 1930s. Public opinion feared an epidemic of sex crimes, and the criminal justice system viewed psychiatrists as a valuable resource. A number of psychiatrists voiced confidence that scientific study of sexual offenders could result in effective prevention and treatment. Many

state legislatures passed sexual psychopath laws including Illinois in 1938, and Michigan and California in 1939.

Psychiatric criminology fueled an interest into psychiatric research involving in-depth analysis into the histories of individual criminals (Karpman 1933; McCartney 1934). In practice, psychiatric attempts to evaluate, treat, and research criminals fell short of the standards proclaimed by the leading psychiatric thinkers of the day (Bromberg 1982). Despite these problems, few psychiatrists heeded voices of caution, such as Menas Gregory who commented that "psychiatry might be over-sold" (Gregory 1935). Despite strong interest and prestige, few psychiatrists actually practiced correctional psychiatry. A survey conducted by McCartney in 1934 revealed 48 full-time and 35 part-time psychiatrists practicing in prisons (Halleck 1965).

Interest in psychiatric criminology waned during the 1940s, as psychiatrists turned their attentions to the psychiatric aspects of the Second World War. Correctional psychiatry services decreased, and efforts toward treatment of offenders became sporadic. Research efforts continued, especially studies in the psychodynamics of psychopathy, which bore fruit during the decade (Cleckley 1941; Wittels 1943; Greenacre 1945). In addition, specialized programs for specific offender populations, especially sex offenders, became established in a number of states. Indeterminate sentencing for sexual offenders became more popular. Psychiatrists generally favored indeterminate sentencing as an important component in a treatment program for criminal behavior using the medical model. However the Group for the Advancement of Psychiatry fiercely criticized indeterminate sexual offender sentencing in 1947, owing to fears regarding due process and the lack of treatment for those receiving indeterminate sentences (Halleck 1965).

The 1950s witnessed a renewed interest in correctional psychiatry and psychiatric criminology. The success of psychoanalytic explanations and treatments for war-related traumatic neuroses spurred a general interest in individual and group therapy. Founded in 1950, the Association for Psychiatric Treatment of Offenders encouraged large-scale individual and group psychotherapeutic treatment for prisoners. Massachusetts instituted an extensive outpatient evaluation and treatment program for probationers and parolees. As correctional psychiatrists engaged in more intensive treatment rather than diagnosis and classification, ethical concerns regarding dual agency became more common (Halleck 1965).

Interest in innovative treatment and reformation of the psychopath resulted in the establishment of the Patuxent Institution in Maryland in 1955. Maryland courts committed "defective delinquents" to the institution under a completely indeterminate sentence until they were rehabilitated, and safe to reenter society. "Defective delinquent" was defined as "an individual who by the demonstration of persistent aggravated antisocial or criminal behavior evidences a propensity towards criminal activity and is found to have either some intellectual deficiency or emotional imbalance or both as to clearly demonstrate an actual danger to society" (*Md.Ann.Code* 1951). Patients received group therapy and individual counseling. An institutional review board evaluated patients for release to the community, which was usually contingent on continued outpatient therapy (Guttmacher 1968).

Wisconsin established a similar program for sex offenders. California opened the Vacaville Medical Facility to provide innovative therapeutic approaches, especially group programming, for prisoners in 1955. The Federal Bureau of Prisons achieved a role as an innovator in correctional psychiatry during this period. Psychiatrists provided a full range of forensic evaluations and innovative treatment programs for the federal prisons during this period (Halleck 1965). Despite these developments, even fewer psychiatrists worked in correctional settings, relative to past periods. A survey by Warren Wille in 1957 found 43 full-time and 35 part-time psychiatrists working in correctional settings. Only 19 state prisons reported having a full-time psychiatrist on staff. Ten states reported no psychiatrists working in any capacity in their correctional systems (Wille 1957).

Correctional psychiatry continued to make a resurgence through the 1960s, and correctional psychiatrists continued to express confidence in their ability to rehabilitate individual prisoners using psychotherapy. In terms of numbers, however, correctional psychiatry during the 1960s remained a minor part of clinical psychiatry. An American Psychiatric Association survey in 1961 indicated that 65 psychiatrists reported spending over 30 hours a week in correctional institutions, with an additional 45 spending at least 15 hours of part-time work or consultation (Halleck 1965). Three years later the chief psychiatrist of the Federal Bureau of Prisons reported that only 56 full-time psychiatrists covered the nations' 230 correctional institutions (Smith 1964).

Leaders in both psychiatry and corrections still envisioned an important role for psychiatry. They believed that psychiatry could contribute "understanding, handling, and, hopefully, correction of socially unacceptable behavior" (Smith 1964). In addition, psychiatry was felt to have a role in modifying the "anti-therapeutic" aspects of incarceration. By the 1960s, some forensic psychiatrists raised doubt about the concept that all criminals suffered from some type of mental illness (Guttmacher 1968).

The optimism expressed early in the decade changed to criticism as the decade ended. Proposals for new innovative programs remained on paper while the real prisoners often received minimal mental health services. Conflicts between psychiatrists and correctional staff impeded the therapeutic mission of correctional mental health services (Stamm 1962). Voices for immediate remedies became prominent. Critics noted that correctional institutions continued to stress security over the psychological needs of prisoners, and they called for action to reform correctional mental health services. (Halleck 1967). Correctional psychiatrists continued to complain that evaluation and treatment of inmates with mental illness were too limiting. Advocacy for primary focus on rehabilitation and for prisons to become

"centers for the study, diagnosis, and treatment of the criminal mind" continued the goals of the Progressive Era (Fink et al. 1969). The 1960s witnessed the beginnings of standards of health care for jails and prisons. In 1966, the American Correctional Association published standards for correctional institutions that included a section on the health care (American Correctional Association 1966).

CORRECTIONAL PSYCHIATRY IN TRANSITION

The 1970s proved to be a time of significant change in correctional psychiatry. Psychiatrists saw their influence in corrections wane, as the concept of rehabilitation came under strong attack. Psychiatrists lost enthusiasm for the coerced psychiatric cure for criminal behavior (Rappeport 1974). Critics of psychiatry questioned the effectiveness and therapeutic authority of correctional psychiatry. A number of prison riots, especially the Attica rebellion in 1971, shook the foundations of corrections. The correctional bureaucracy began to question the utility of correctional psychiatry, as faith in rehabilitation for prisoners faded. Prison and jail inmate populations exploded and placed severe pressures on correctional systems. Overall, psychiatrists became more modest in their therapeutic goals (Roth 1986). Correctional psychiatry lost prestige and appeared unappealing to many if not most clinicians (Cumming and Soloway 1973).

The Supreme Court and lower courts significantly increased constitutional protections for prisoners' rights. Prior to 1973, the courts allowed prison administrators a free hand in running prisons, including the restrictions of civil rights. For example, the Virginia Court of Appeals ruled in 1871 that "Prisoners have no more rights than slaves" (*Ruffin v. Commonwealth* 1871). A number of Supreme Court and Appeals Court rulings greatly expanded the basic constitutional rights of prisoners. In 1974 the Supreme Court clearly affirmed a basic set of prisoner rights (*Wolff v. McDonnell* 1974). The Fifth Circuit Court of Appeals ruled that lack of mental health care could violate a prisoner's eighth amendment protections (*Newman v. Alabama* 1974). The landmark case *Estelle v. Gamble* (1976) set a standard for the provision of medical care for prisoners. *Estelle v. Gamble* held that inadequate medical care constituted cruel and unusual punishment. The U.S. Supreme Court established a "deliberate indifference" standard of medical care. In 1977, the Fourth Circuit Court of Appeals ruled that the right to mental health care was equal to a prisoner's right to medical care in *Bowring v. Godwin* (1977). The Supreme Court ruled on a prisoner's due process rights when transferred from a prison to a psychiatric hospital in *Vitek v. Jones* (1980). The court ruled that such transfers required procedural safeguards, including an administrative adversarial hearing with available legal counsel due to stigmatization and other "curtailment of liberty."

Research into antisocial behavior continued, but the emphasis in jails and prisons was to treat mentally disordered prisoners. Commentators increasingly questioned psychiatry's attempts to treat antisocial behavior, even in those individuals with other mental illnesses. Critics asserted that psychiatrists and other mental health professionals could not demonstrate the effectiveness of coerced treatment on patients engaging in antisocial behavior, and that the mental health system perpetuated myths about the curability of this population. John Monahan, for example, complained of the "psychiatrization of criminal behavior" (Monahan 1973). Critics in and out of psychiatry questioned the effectiveness and moral basis of sexual psychopath laws. States progressively phased out commitment laws and traditional treatment programs (Group for the Advancement of Psychiatry 1977).

By the early 1970s, many psychiatrists feared that changes making involuntary commitment laws more stringent would force many individuals with mental illness into the criminal justice system. (Abramson 1972; Kirk and Therrein 1975; Rachlin et al. 1975). Steadman's research to address this question cautioned that perceptions of increasing numbers of mentally ill inmates in prisons and jails were not supported by statistics (Steadman and Ribner 1980).

For the most part, the 1980s represented a period of consolidation for correctional psychiatry. Turning from a focus on societal goals, correctional practitioners focused on dealing with particular problems of mental health service delivery in the correctional environment, and on evaluation and treatment of individual prisoners (Roth 1986). The prestige of correctional psychiatry remained low. Critics from within psychiatry pointed out a number of perceived problems with correctional psychiatry: isolation from mainstream clinical practice, collusion with correctional authorities, professional legitimization of dehumanizing, coercive institutions, and poor working conditions. Correctional psychiatry positions seemed dangerous, unpleasant, and poorly paid (Goldstein 1983).

Inmate populations continued to grow rapidly due to increased conviction rates and the gradual shift to determinate sentencing. Social critics continued to criticize the mental health care provided in jails and prisons. Criticisms included the lack of specialized mental health housing units, misuse of psychotropic medications, overuse of restrictive interventions, and general prison conditions that contributed to prisoner psychopathology (Kaufman 1980, Hollingsworth 1985, Schulte 1985).

The 1980s saw the beginning of concerted efforts to create standards for correctional mental health care and the progressive differentiation of correctional psychiatry from other branches of the profession. The National Commission on Correctional Health Care published a set of health-care standards for jails, prisons, and juvenile detention centers (National Commission on Correctional Health Care 1986a; National Commission on Correctional Health Care 1986b). These efforts were supplemented by standards published by the American Bar Association in 1989. In 1989 the American Psychiatric Association published suggested guidelines for

mental health-care standards in jail and prisons (American Psychiatric Association 1989).

THE NINETIES

Jail and prison populations continued to escalate during the 1990s, which fueled demand for more mental health services. Correctional mental health services, however, lagged behind (Manderscheid 2004). State legislatures and departments of correction searched for a solution to rising prison populations, limited prison beds, class action lawsuits, and growing costs of incarceration. Reflecting developments in the community, managed mental health appeared to be an effective way to curb costs, yet provide mandated services (Patterson 1998).

In a related development, various state departments of correction and the federal government experimented with privatization of prisons. In addition a number of states privatized correctional health care and mental health care in a bid to decrease the burden on budgets imposed by state-operated services. Large, for-profit companies such as Corrections Corporation of American, Wackenhut Corrections Corporations, and Prison Health Services managed prisons and health services beginning in the 1980s. A number of state legislatures and departments of corrections viewed these companies as the solution to their problems.

Proponents argued that privatization provided significant cost savings by the mechanism of competition-driven private-sector efficiency and innovation. Private-sector companies promised to provide the equivalent quality of service and save money by avoiding the bureaucratic obstacles, staff costs, and entrenched practices of state-operated correctional services. Critics of privatization warned that the quality of services would be compromised by profit consideration. Some accused corporations of underbidding in order to get a foothold in the state contracts. Critics also charged that private mental health centers provided overly restrictive formularies, restricting diagnostic testing, and decreasing lengths of stay (Schneider 1999; Swanson 2002). Newspapers alleged significant problems with correctional mental health services (Hurst 1995; Kurkjian 1996; Corcoran 1999a,b). Overall, critics characterized the state of prison mental health as woefully inadequate, cruel, and the by-product of a corrupt "prison–industrial complex" (Kupers 1999).

Eventually pressures on managed care resulted in increased health-care costs, and the same trend became evident in correctional mental health services. According to critics, competition between managed care companies resulted in instability, as contracts switched from company to company. Private corrections companies and managed health service providers continued to merge. The departments of correction experienced increased need for mental health services and limited resources resulting in shortened lengths of stay on mental health units (Allen and Bell 1998; Marshall 2000).

The courts continued to clarify and tighten prisoner rights during the decade. The Supreme Court clarified the definition of deliberate indifference regarding cruel and unusual punishment in *Farmer v. Brennan* (1994). The court ruled that prison officials were liable for cruel and unusual punishment if they knew that the inmate faced a substantial risk of harm, but disregarded that risk. The Supreme Court ruled on the involuntary administration of psychotropic medications to prisoners in *Washington v. Harper* (1990) and *Riggins v. Nevada* (1992) based on Fourteenth Amendment rights. In *Washington v. Harper*, the court ruled that psychotropic medications could be involuntarily administered if the treatment arose from "legitimate penological interests" and if the prisoner received institutional due process protections. Two years later, the *Riggins v. Nevada* decision ruled that pretrial detainees could not be involuntary treated with psychotropic medications unless the government established a need for treatment.

Research efforts in the 1990s concentrated on epidemiological studies to determine mental health service requirements. In addition, research efforts analyzed the provision of mental health services in specific institutions in light of mental health-care standards. Such research led to a promising analytic approach to understanding and improving correctional mental health services by utilizing a systems approach (Metzner 1997a,b, 1998). Epidemiological studies continued to demonstrate a high prevalence of mental illness and substance abuse in populations of prisoners (Teplin 1990; Teplin et al. 1996; Lamb and Weinberger 1998).

THE TWENTY-FIRST CENTURY

The new century witnessed continuing demand for correctional mental health services. Although the total prison population peaked during the first decade of the century, the United States continued to lead the world in the use of incarceration. Mental illness in correctional populations continued to be viewed to be in crisis (Aufderheide and Brown 2005). Advocates and popular media criticized the apparent movement of mentally ill individuals from the mental health system to the criminal justice system; characterized as criminalization of the mentally ill (Slate et al. 2013; Ford 2015).

The turn of the century did not usher in major changes to the roles and responsibilities of correctional psychiatrists. Perhaps one substantive change to basic practice was the adoption of telepsychiatry by correctional psychiatrists (or those who employed them) (Antonacci et al. 2008). A number of controversial issues emerged (or re-emerged) that presented challenges to the field and other correctional health-care providers. Correctional psychiatrists actively contributed to ongoing debates regarding solitary confinement (Metzner 2010), supermax prisons (Dvoskin and Metzner 2006), administrative segregation (O'Keefe et al. 2013), seclusion and restraint (Appelbaum 2007),

suicide prevention (Daniel 2006), professional boundary and ethical issues (Metzner 2008), transgender populations (Simopoulos and Khin 2014), and involuntary medication of inmates (Salem et al. 2015), among others.

Litigation remained the mainspring for correctional reform. In *Brown v. Plata*, decided in 2011, the Supreme Court ruled that the State of California violated the Eighth Amendment rights of California prison inmates by housing them in overcrowded conditions and failing to provide constitutional levels of health services. The Court upheld a U.S. District Court decision that ordered California to reduce its prison population to 137.5% of design capacity within 2 years. Psychiatrists with correctional expertise played roles in providing consultation to the courts and states (Metzner 2002).

Practice standards and guidelines for correctional mental health care continued to be actively updated (Hills 2004; Thienhaus and Piasecki 2007; National Commission on Correctional Health Care 2015a). Private corporations continued to grow their share of the correctional healthcare market, both in private prisons and as contractors to state-operated facilities. These companies remained sources of employment for correctional psychiatrists but advertised cost savings by using physician extenders. Corporate mergers remained a characteristic of the industry. For example, Corizon Health was formed in 2011 when Correctional Health Services (CHS) joined with PHS Correctional Healthcare (Corizon Health 2011). Provision of correctional mental health services by contracted academic medical centers was proposed as an alternative to for-profit providers (Appelbaum et al. 2002). Several such partnerships, however, did not survive competition from private providers.

The twenty-first century witnessed the maturation of correctional psychiatry into a distinct subspecialty. Academic activity and research in the field became increasingly more prominent in journals such as the *Journal of the American Psychiatry and the Law*. Publication of handbooks, manuals, and texts devoted to correctional psychiatry further reinforced the distinctiveness of the field (Scott 2010; Trestman et al. 2015). Psychiatry training programs experimented with incorporating correctional psychiatry rotations into their curricula (Fuehrlein 2014). In addition to publishing practice guidelines and accrediting correctional facilities, the National Commission on Correctional Health Care added specialty certification for mental health professionals to existing certification programs for correctional health professionals and nurses in 2013 (National Commission on Correctional Health Care 2015b).

Correctional psychiatrists rightly continue to focus on providing better clinical service for their patients; however, the field is claiming a more prominent role in the public policy, litigation, and research aspects of corrections. Developments in corrections and correctional mental health systems continue to provide psychiatrists and other mental health professionals with opportunities for leadership and innovation (Halpern 1998).

SUMMARY KEY POINTS

- Much of the history of correctional psychiatry in the United States has been driven by long-standing interests in explaining and treating criminal behavior by social reformers and physicians which reached a peak during the first half of the twentieth century.
- During the 1970s, a consensus of U.S. policy makers lost faith in the ability of psychiatrists to treat criminal behavior and concluded that rehabilitation of prisoners did not work.
- The 1980s and 1990s witnessed the development of correctional psychiatry into a distinct subspecialty through the formation of professional organizations, institutional standards, and treatment guidelines. Simultaneously correctional mental health systems were forced to cope with a massive explosion in prison populations.
- Despite challenges, correctional psychiatry has continued to mature during the twenty-first century. The field has continue to strive for improved clinical services and taken a more prominent role in, public policy, litigation, and the research aspects of corrections.

Overview of correctional psychiatry

CHARLES L. SCOTT

INTRODUCTION

The U.S. correctional system is one of the largest providers of mental health care to its citizens. According to E. Fuller Torrey (1999), the Los Angeles County Jail houses 3400 inmates with mental illness, making it the largest psychiatric inpatient facility in the United States. In some jurisdictions more mentally ill receive treatment in the local jail or prison than in the community. What might explain this dramatic shift? The deinstitutionalization of individuals with chronic and severe mental illness from hospitals into the community has been cited as one of the most significant contributors to the rising population of offenders with mental illness behind bars. With the closure of many psychiatric facilities and limited community resources to treat individuals with chronic and severe mental illness, it is not surprising that many of these same persons have found their way into the criminal justice system (Lamb and Weinberger 2013).

Correctional environments are significantly different than hospital and community treatment settings. This chapter provides a definition of "corrections," highlights purposes of punishment, describes types of correctional settings, reviews stages of the criminal justice system, explains inmate classification schemes, and outlines the process governing the return of inmates to society.

DEFINITION OF CORRECTIONS

The term "corrections" includes those agencies and programs at the local, state, and federal level that oversee individuals who have been either accused of crimes or convicted of them. Police, prosecutors, and courts play an integral role in determining whether an individual enters the legal system and is subject to imposed controls from a correctional agency (Silverman 2001). Correctional settings are wide ranging and include lockups, jails, and prisons. Correctional mental health includes the provision of mental health assessment and treatment in a correctional setting.

The criminal justice system was created to address those actions committed by individuals that violate laws against society. These violations of laws are generally referred to as crimes. According to the 2013 National Crime Victimization Survey (NCVS), 10.2% of U.S. households have experienced at least one violent or property crime (Truman and Langton 2014). Each state and the federal government have a criminal code that defines specific crimes and associated sentences. In general, charges are likely to be filed in federal court when there is either: (1) an alleged violation of federal, as opposed to state law; or (2) if the alleged crime took place on federal property. The most common crimes referred to federal court include controlled substance violations, immigration law violations, mail or wire fraud, gun laws, postal offenses, child pornography, counterfeiting, and crimes that occur on federal property or in federal buildings (Federal Crime Cases 2015). Charges are filed in state court when an individual has violated a specific state statute and the alleged crime is not covered under federal jurisdiction.

THEORIES OF PUNISHMENT

For centuries, societies have established basic rules that govern how their citizens live with similarly established punishments for violating those rules. Why does society punish its citizens for their wrongdoing? Four classic theories of punishment help answer this question and include retribution, deterrence, rehabilitation, and incapacitation.

Retribution

Retribution involves the use of punishment in response to a law-violating act simply because the offender deserves it. This approach emphasizes that those who cause harm should be subject to punishment as a result. Early legal systems used retribution almost exclusively as the primary principle to punish offenders. This approach was referred to as *lex talionis*, or "the law (lex) of retaliation." Under the law of *lex talionis,* equal and exact retribution was exacted, as demonstrated in the words of the Hebrew scripture, "an eye for an eye, a tooth for a tooth, an arm for an arm, a life for a life" (Hooker 1997).

The concept known as "just desserts" is the modern equivalent of *lex talionis*. Although the individual is punished because his or her act deserves punishment, the "just deserts" approach allows consideration of punishment proportional to the severity of the crime, whereas this is not typically considered under strict retribution theory. It is important to note that the retribution principle is nearly entirely retrospective.

Deterrence

Under the theory of deterrence, punishment is imposed to deter or prevent individuals from committing a future criminal act. The concept of deterrence involves both specific and general deterrence. The concept of specific deterrence theorizes that imposing sanctions on an individual who has broken the law will make that individual less likely to violate the law in the future. In contrast, general deterrence theorizes that when citizens who have never offended become aware that other people are punished for illegal behavior, they will be less likely to commit an offense due to their fear of legal consequences.

The effectiveness of specific deterrence in preventing individuals in committing future offenses is questionable. In particular, nearly 70% of state prisoners released in 2005 were arrested within 3 years of release, and over 75% were arrested within 5 years of release (Durose et al. 2014). At the same time, nearly a quarter of all offenders did not reoffend, suggesting that a significant minority are deterred from future criminal acts. Other studies indicate that in some situations, punished individuals are specifically deterred from future offenses. For example, arrested drunk drivers (Shapiro and Votey 1984), first-time offenders (Smith and Gartin 1989), and spouse abusers (Sherman and Berk 1984) who received severe punishment were less likely to violate the law upon release when compared to those who received more lenient sentences. Three factors that are believed to affect the success or failure of criminal sanctions include the severity, the certainty, and the swiftness of punishment (Silverman 2001).

Rehabilitation

According to the rehabilitative theory of punishment, individuals are incarcerated in order to learn socially appropriate behaviors to replace their deviant actions. Correction, therefore, is designed to treat those traits that result in criminal behavior. The rehabilitative model argues that the purpose of incarceration is to reform inmates through educational, training, and counseling programs. The rehabilitative approach to managing criminal offenders was prominent following World War II until the 1960s (Silverman 2001). However, as the majority of released prisoners reoffended despite this rehabilitative approach, Americans became increasingly skeptical about the rehabilitative model of punishment. A published review of rehabilitation programs for inmates by New York sociologist Robert Martinson and colleagues contributed to the belief that rehabilitation programs for offenders had minimal benefit. This research reviewed 231 studies of offender rehabilitation programs conducted between 1945 and 1967 (Lipton et al. 1975). In his famous 1974 article titled "What Works? Questions and Answers about Prison Reform," Martinson interpreted the results from the above research. In this article he concluded, "with few and isolated exceptions, the rehabilitative efforts that have been reported so far have had no appreciable effect on recidivism." He emphasized, "Our present strategies… cannot overcome, or even appreciably reduce, the powerful tendencies of offenders to continue in criminal behavior" (Martinson 1974).

Martinson's article was widely read, and his published findings on rehabilitation were quickly renamed, "Nothing works!" His persuasive arguments had far-reaching effects and played a significant role in the American penal system moving away from the rehabilitative approach for offenders. Subsequent reviews of rehabilitation programs did not replicate Martinson's findings and utilized statistical analysis of treatment outcome not available to Martinson. In their survey of 200 studies on rehabilitation conducted from 1981 to 1987, Gendreau and Ross (1987) concluded that successful rehabilitation of offenders was possible and up to 80% reduction in recidivism had been noted in research studies examining effective programs. Despite these more encouraging results, the pendulum had already moved away from rehabilitation as a purpose for punishment. As a result, a harsher theory of punishment, known as incapacitation, became increasingly popular throughout the United States.

Incapacitation

Under the incapacitation principle, individuals are prevented from committing future criminal acts by holding them against their will in a secure environment. A sentence of life without the possibility of parole represents a more extreme form of incapacitation. The ultimate form of incapacitation is the imposition of the death penalty. With public concern increasing alongside the rising crime rate during the late 1980s and 1990s, many state legislatures passed laws that resulted in longer sentences. But not all incapacitation is the same. In general, there are three forms of incapacitation. Under a schema known as *collective incapacitation*, all offenders convicted of the same crime receive the same sentence. The anticipated effect of collective incapacitation is a substantial increase in the prison population as there is no attempt to distinguish between high- versus low-risk offenders (Cohen 1983; Silverman 2001). In contrast, *selective incapacitation* incarcerates only those offenders who are predicted to be at higher risk for reoffending. Legislative efforts to increase the length of incapacitation for higher-risk offenders have resulted in significant sentencing reform over the last three decades. These reforms include "truth in sentencing" (TIS) schemes and the passage of "three strikes you're out" statutes. TIS laws require offenders to serve a substantial portion of their prison sentence with restrictions

on both parole eligibility and good-time credits (Ditton and Wilson 1999). Under "three strikes you're out" statutes, felons found guilty of a third serious crime can be incarcerated for 25 years to life, even if the felonies themselves were relatively minor. A third incapacitation approach is called *criminal career incapacitation*. Under this scheme, classes of criminals (rather than all criminals) with known high rates of crime receive longer sentences (Silverman 2001).

The increasing use of incapacitation as punishment resulted in a corresponding increased prison population between 1990 and the mid-2000s. Although there has been a slight downward trend in the total U.S. correctional population since 2007, nearly 1 in 35 adults in the United States remained under some form of correctional supervision as of December 2013 (Glaze and Kaeble 2014).

TYPES OF CORRECTIONAL FACILITIES

The U.S. correctional system is complex and includes a federal system, 50 separate state systems, and thousands of local systems. Each individual state determines its own criminal justice and correctional system with resulting differences in how crimes are defined, who is arrested, and what consequences are imposed for law violating behavior (Silverman 2001). Correctional housing facilities vary and are broadly classified into three types of facilities: lockups, jails, and prisons.

Lockups and jails

Lockups are local temporary holding facilities that constitute the first level of detention in many jurisdictions. The lockup is the most common type of correctional facility with an average stay usually lasting less than 48 hours. Lockups are often located in the local police station where only temporary detainment (e.g., arrestees charged with driving under the influence) is required. Approximately 30% of local police departments operate at least one lockup facility for adults separate from a jail. In jurisdictions with 500,000 or more residents, local lockups can detain up to 70 individuals, whereas lockups in jurisdictions with fewer than 10,000 residents typically house about three persons (Reaves and Goldberg 2000). In those jurisdictions that do not have a lockup facility, the individual arrested is detained in the local jail.

Jails are locally operated correctional facilities that hold persons before or after their trial. Individuals who are convicted of a misdemeanor (minor crime) receive a sentence of a year or less and complete their sentence in a jail, not a prison. Jails serve the following functions: holding detainees awaiting trial; holding those convicted of a misdemeanor who are serving their sentence; detaining violators of probation, parole, or bail; temporary detention of juveniles pending transfer to juvenile authorities; holding of mentally ill persons pending their movement to appropriate health facilities; transfer of inmates to federal, state, or other authorities; holding of individuals for the military, protective custody, contempt, or for the courts as witnesses; and sometimes operating community-based programs as alternatives to incarceration.

In some situations, individuals facing federal charges may also be detained in a local jail. For example, the U.S. Citizenship and Immigration Services (USCIS) have the authority to detain certain categories of noncitizens. The Marshals Service assumes custody of persons arrested by all federal agencies and is responsible for the custody of more than 220,000 federal prisoners. In jurisdictions where detention space is limited, the Marshals Service utilizes Cooperative Agreement Program (CAP) funds to improve local jail conditions in exchange for guaranteed space for federal prisoners (U.S. Marshals Service 2014).

Of the total incarcerated population in the United States, approximately one-third are held in local jails (Glaze and Kaeble 2014). At midyear 2013, 731,208 persons were held in local U.S. jails (Minton and Golinelli 2014). Of individuals detained in jail, approximately 60% are awaiting some type of court action on their current charge while the remaining inmates are serving time for their conviction (Minton and Golinelli 2014). The following findings characterize the U.S. jail inmate population: nearly half (46%) are on probation or parole at the time of their arrest; half have been using drugs or alcohol at the time of their offense; half are held for a violent or drug offense; over half grew up in a single-parent household; and nearly half (46%) had a family member who had been incarcerated (James 2004). Of jail inmates identified as mentally ill, over 30% were homeless in the year prior to the arrest compared to 17.3% of jail inmates without an identified mental disorder (Ditton 1999).

Prisons

Prisons are confinement facilities that maintain custodial authority over inmates who have been convicted of felonies. A felony is a more serious crime than a misdemeanor. The imposed sentence for a felony is greater than 1 year at a minimum. Prisons are operated by both state and federal governments and are typically large facilities, often with over 500 beds. More inmates serve their time in prisons when compared to jails. In particular, approximately one-third of all correctional inmates are incarcerated in jails, whereas two-thirds serve their time in a prison (Glaze and Kaeble 2014). The Federal Bureau of Prisons (BOP) was established in 1930. The federal prison system includes a nationwide system of 116 detention facilities responsible for the custody and care of nearly 210,000 federal offenders (About the Federal Bureau of Prisons 2011).

Thirty states and the federal system contract with private agencies to hold prisoners in privately operated facilities. An increase in private contracting of correctional beds has arisen to alleviate overcrowding in the state and federal system and to quickly obtain beds as the incarcerated population increases (McDonald et al. 1998). In 2013, private facilities housed 133,000 inmates, and this number

represents 7% of all prisoners under state or federal jurisdiction (Carson 2014).

Prison demographic data demonstrate inequalities based on ethnicity, age, and gender. For decades, minority males have been overrepresented among prison inmates. At year-end 2013, Hispanic males comprised 22% of sentenced males, white males comprised 32% of sentenced males, and black males comprised 37% of sentenced males (Carson 2014). Men continue to dominate the prison population and are nearly 13 times more likely than women to be incarcerated in a state or federal prison. However, the face of the typical prison inmate as one of a young male is slowly changing. Between 2012 and 2013, female prisoners sentenced to more than a year in state or federal prison grew by nearly 3%, while male prisoners increased only 0.2% (Carson 2014).

Prison inmates are also getting older. Between 1995 and 2010, the number of state and federal inmates age 55 or older nearly quadrupled (Old Behind Bars 2012). The increasing length of sentences under mandatory sentencing schemes has contributed to the aging of the correctional population. Because inmates have a constitutional right to medical care, states and counties will likely face substantial financial burdens related to aging inmates who will require increasingly costly medical interventions.

OVERVIEW OF THE CRIMINAL JUSTICE PROCESS

Although the U.S. system of justice originates from English common law, there is no uniform criminal justice system in the United States. Often criminal actions are not discovered or reported to law enforcement agencies (The Justice System 2015). The majority of crimes are not solved. Under the Uniform Crime Report (UCR) Program, once a crime is reported to law enforcement, it is designated as "cleared" if at least one person is arrested, charged with the commission of an offense, and turned over to the court for prosecution. In 2013, law enforcement agencies cleared 48.1% of violent crimes (murder, forcible rape, robbery, and aggravated assault), 19.7% of property crimes (burglary, larceny-theft, and motor vehicle theft), and 20.7% of arson offenses (Federal Bureau of Investigation 2014).

Despite some variation in the handling of criminal cases between various jurisdictions, the most common sequence of steps in response to known criminal behavior is as follows. An individual becomes a suspect in a crime following reports from victims, other witnesses, discovery by a police officer, or from investigative work. For most crimes, especially minor crimes, police officers serve as gatekeepers in determining which persons will formally enter into the justice system. This discretionary arrest authority provides officers options other than taking the person into custody. For example, officers can warn offenders and release them or divert an offender to a mental health treatment program. In dealing with juveniles, the officer can bring the youth home and informally discuss the juvenile's behavior with the family (Finn and Sullivan 1988).

An arrest involves the taking of an individual into custody under the legal authority granted by the government. Law enforcement practices regarding who is arrested and why they are arrested vary according to the jurisdiction. In 2013, law enforcement made approximately 11.3 million arrests in the United States. Drug abuse violations represented the most common offense type for which individuals were arrested followed by larceny-theft and driving under the influence (Federal Bureau of Investigation 2014).

Individuals who are arrested or charged with an offense are usually taken to the police station or local jail for booking. The booking process has many administrative steps. This process includes taking the individual's mug shot, recording personal information, fingerprinting, assigning identifying case numbers, conducting medical and psychiatric screening, and beginning a new file for first time arrestees. Nearly half of those individuals who are arrested will leave the jail within 24–48 hours after they are booked. Inmates who are not released are thoroughly searched, their property is removed, and they are issued standard jail clothing (Silverman 2001).

Following the individual's arrest and subsequent booking, law enforcement agencies provide information regarding the accused to the prosecutor. Prosecutors have broad discretionary authority. They play a significant role in determining whether to initiate prosecution and what specific charges will be filed with the court. If no charges are filed, the accused must be released. At this stage, there are several alternatives to a formal filing of charges. The prosecutor may request that the judge enter a *nolle prosequi*. *Nolle prosequi* is defined as a formal entry upon the record by the prosecuting officer in a criminal action, by which he declares that he "will no further prosecute" the case, either as to some of the defendants, or altogether. This is commonly referred to as "Nol Pros" (Silverman 2001; The Justice System 2015).

Second, for individuals already involved in the criminal justice system, the prosecutor may decide to revoke probation or parole rather than initiate new charges. Third, the suspect may be civilly committed to a mental health treatment facility. Fourth, a decision to invoke civil sanctions, such a revocation of a person's license, may substitute for processing the arrestee through the criminal justice system. Charges may also be reduced or dismissed in those situations where the victim is unwilling to cooperate with prosecution or for suspects who agree to testify for the prosecution or act as an informer (Silverman 2001).

If a suspect is charged with a crime, he or she is taken before a judge or magistrate. At this initial appearance, the judge must inform the accused of the charges and decide whether there is probable cause to detain the individual. Probable cause exists when there is a reasonable belief that a crime has or is being committed and is the basis for all lawful searches, seizures, and arrests. For nonserious offenses, the judge or magistrate may determine guilt and assess a penalty at this stage. Defense counsel may also be assigned

at this initial appearance. All suspects charged with serious crimes have a right to be represented by an attorney. The court assigns an attorney for indigent suspects who cannot afford their own counsel (The Justice System 2015).

Following the assignment of a defense attorney, the accused has an initial appearance, where the court may decide to release the accused prior to trial. For individuals released prior to trial, the court may set bail (The Justice System 2015). Bail is money that a defendant must provide up front (often through a contract with a bail bondsman) that must be forfeited if the accused fails to appear in court for trial. The amount of bail set is governed by multiple factors including the seriousness of the charges, the risk of flight from the governing jurisdiction, past legal history of the defendant, and the financial status of the defendant.

Depending on the locality, a preliminary hearing may follow the initial appearance of the defendant in court. The primary purpose of this hearing is for the court to determine if there is sufficient evidence of probable cause that the accused committed a crime. In situations where the judge does not find probable cause, he or she must dismiss the case. If probable cause is found or if the accused waives his or her right to a preliminary hearing, then the case may be forwarded to a grand jury (The Justice System 2015).

During the hearing before the grand jury, the prosecutor presents the evidence against the accused and the grand jury decides whether the evidence warrants the accused being brought to trial. If the grand jury determines there is sufficient evidence, then they submit an indictment to the court. An indictment is a written summary of the facts of the offenses charged against the accused. In some jurisdictions, both misdemeanor and felony cases move forward after a document known as the "issuance of information" is provided. The issuance of information is a formal written accusation that the prosecutor submits to the court. The accused may choose to waive a grand jury indictment and accept the service of information (The Justice System 2015).

Following an indictment or filing of an issuance of information with the court, the accused is then scheduled for an arraignment. An arraignment is a hearing where the accused is informed of the charges, advised of their rights, and requested to enter a plea. In some situations, the defendant may choose to enter either a plea of guilty or *nolo contendere.* A plea of *nolo contendere* indicates that the defendant accepts his or her penalty without admitting guilt. If the judge accepts a guilty or *nolo contendere* plea, a trial is not held and the case proceeds to the sentencing phase (The Justice System 2015).

In situations where the defendant pleads not guilty or not guilty by reason of insanity, a trial date is scheduled. In serious crimes, the defendant is guaranteed a right to trial by jury, though may choose to have a "bench trial" where the judge, rather than a jury, hears the case and determines guilt. At the trial, the defense and prosecution both present evidence, and the judge decides on issues of law. At the conclusion of the trial, a finding of guilty or not guilty is made. Next, the defendant is scheduled for a sentencing hearing where both mitigating and aggravating factors are presented.

Courts often review presentence investigations, completed by probation agencies, along with victim impact statements, in deciding the appropriate sentence for the convicted offender. Mental health professionals are frequently called on to present information regarding the defendant's psychiatric history as part of the sentencing process. Following the trial, the defendant may appeal his or her conviction or sentence. All states with a capital punishment provision provide an automatic appeal for defendants who receive the death penalty (The Justice System 2015).

The range of sentencing options include incarceration in a prison, jail, or other confinement facility, or release into the community on probationary status. Probation allows those convicted to remain in the community under specified restrictions such as drug testing or required treatment programs. At year-end 2013, 4,751,400 men and women were on probation (Herberman and Bonczar 2014). The court may also require the convicted offender to pay a fine or make restitution through financial compensation to a victim. Certain jurisdictions provide other alternatives to incarceration that are more intense than regular probation requirements though do not require actual incarceration. Such programs include boot camps, house arrest with electronic monitoring, intense supervision with mandated drug and/or psychiatric treatment, and community service.

INMATE CLASSIFICATION

Classification attempts to match inmates with the appropriate level of security, custody supervision, and services necessary to meet their needs. Appropriate classification is important for the following five reasons: protection of inmates; protection of the public; maximizing efficient use of resources; controlling inmate behavior; and providing planning information for budgets, staffing, and program development (Silverman 2001).

For individuals who are serving time in jail, the classification procedure typically occurs in the jail in which they are housed. As a result of this process, the inmate may be placed in a particular housing unit within the jail based on security, medical, and/or mental health needs. For those individuals sentenced to prison, the location of the classification process depends largely on the inmate's jurisdiction. In some areas, inmates are sent to a central reception and diagnostic center after they are sentenced. After an evaluation of the level of security and special services required, the inmate is transferred to the most appropriate matched facility. In other jurisdictions, the inmate undergoes the classification process in a prison reception unit where they are kept until this process is completed. The inmate is then placed in general population or transferred to another facility if needed.

Classification involves determination of both the security and custody level appropriate for the inmate. Facility security level has been defined as "the nature and number of physical design barriers available to prevent escape and control inmate behavior" (Henderson et al. 1997). Jurisdictions vary regarding how they define security levels for their correctional institutions. The Federal Board of Prisons (BOPs) guidelines provide one example of how a security-level system is determined. The BOPs security classification scheme includes four recommended security levels. Level I prisons are referred to as minimum security facilities or federal prison camps. These facilities are characterized by dormitory housing without a surrounding fence and a relatively low staff-to-inmate ratio. Level II facilities are termed "low-security institutions" and are typically surrounded by double fenced perimeters. These facilities have strong work and program components with a higher staff-to-inmate ratio when compared to a minimum security facility. Level III facilities, i.e., medium-security institutions, have more secure perimeters with electronic detection systems, cell-type housing, and greater staff-to-inmate ratios compared to level I and II facilities. Level IV facilities are considered high-security institutions. Their perimeters are often significantly reinforced and may consist of walls with towers at each corner manned by armed correctional officers. Housing in a level IV facility is primarily single- or multiple-occupant cell housing and close staff supervision, and movement control is characteristic (Silverman 1991).

Whereas the security level refers to the number of environmental barriers to prevent escape or manage behavior, an inmate's custody level is determined by the degree of staff supervision necessary to provide adequate control of the inmate (National Institute of Corrections 1987). Under the Federal Bureau of Prison classification scheme, inmates noted as "out custody" have a relatively greater degree of freedom of movement compared to higher-level-custody inmates. For example, such inmates may be assigned to less secure housing as they are eligible for work detail outside the secure perimeter of the institution, with decreased levels of staff supervision. Inmates classified as "in custody" are typically assigned to regular quarters, may have work assignments under normal levels of supervision, and are not allowed to participate in work programs outside the confines of the institution. A "maximum custody" classification label is the highest custody level assigned and requires intense control and supervision. This classification is generally given to those inmates who demonstrated violence, who had disruptive behavior, or who pose a serious escape risk (Silverman 2001).

Prison environments vary regarding the type of inmate received, and the level of security and staffing. Traditionally, inmates who have received the death penalty have been segregated into separate housing areas known as death row. Because persons who receive the death penalty have been viewed as dangerous and/or an increased escape risk, separate secure housing pods with increased supervision and correctional officer staffing were deemed necessary.

With the increasing financial burdens associated with longer periods on death row, some states have developed opportunities for inmates who have received the death penalty to be mainstreamed into the general population and/or to participate in work programs while on death row. Benefits for correctional administration cited by these policies have included cost savings, reduction in legal expenses regarding defense of standard of care law suits, and greater flexibility with the use of bed space. Advantages for inmates resulting from these emerging policies include increased access to legal resources, recreation time, commissary, visitation, medical care, and work programs (Silverman 2001).

No longer do inmates have to be convicted of a capital crime to be housed on a special security unit. During the last few decades, several jurisdictions have built or modified existing prison facilities that create highly isolated environments for those inmates considered too dangerous to be maintained in a general prison population. These facilities are known by various names to include "extended control facility," "supermax," "maxi-max," or a "security housing unit" (SHU). Often labeled a prison within a prison, these tightly managed facilities provide control of inmates who have exhibited violent or seriously disruptive behavior while incarcerated and as a result cannot be maintained in a less restrictive environment. In 1963, the U.S. Penitentiary at Marion, located in southern Illinois, was opened to replace Alcatraz and was the highest maximum security prison in the United States. Inmates in these types of facilities are often kept in their cells for up to 23 hours a day with minimal, if any, interaction with other inmates.

RELEASE FROM PRISON

The exact amount of time an offender serves in prison depends on the type of sentencing scheme outlined in the reviewing jurisdiction. Each state's penal code provides sentencing guidelines, which are minimum and maximum time frames to be imposed for each offense. An indeterminate sentencing scheme provides a minimum time period the inmate must serve and a maximum time period after which the inmate must be released (Silverman 2001). Under an indeterminate sentencing scheme, a parole board (or other reviewing agency) considers whether it is appropriate for the individual to be released and placed into the community.

As a result of increasing public skepticism regarding the rehabilitative potential of inmates and appropriateness for early release, indeterminate schemes have lost their popularity over the last several decades. In their place, more jurisdictions are adopting determinate sentencing schemes. A determinate sentencing scheme outlines a specified number of years that the individual must serve based on

the committing offense. Under a determinate sentencing scheme, the time sentenced cannot be increased or decreased. Although determinate sentences are fixed, an inmate may be granted an earlier release date through the accumulation of "good time." Depending on each jurisdiction's statutory provision, good time credits can be earned through either automatic or earned credits. Credits can be earned through participation in work or treatment programs (Silverman 2001).

Under both determinate and indeterminate sentencing schemes, a prisoner may be released prior to completing his or her sentence through the process known as parole. Parole represents the conditional release of the offender into the community. Under an indeterminate sentencing scheme, a parole board (or similarly designated authority) decides whether the inmate should be granted an early release. If the inmate is released, a separate process known as parole supervision begins, which provides support, monitoring and supervision, and services to the newly released offender. Two important components often considered when deciding the appropriateness of parole include the severity of the offense and the inmate's risk of reoffending.

Inmates who have been sentenced under a determinate sentencing scheme are required to serve out their full sentence less any credits for participation in programs (known as good time credits). Those convicted offenders who are released into the community under parole remain under the supervision of the parole officer. They must adhere to specified conditions of parole for the remainder of their unexpired sentence. Failure to adhere to the conditions of parole can result in the offender being returned to prison to complete his or her sentence.

SUMMARY KEY POINTS

Mental health practitioners play a variety of vitally important roles in the assessment, treatment, and management of offenders at virtually every point along their journey through this complex system. Key points from this chapter include the following:

- There are four theories of punishment: retribution, deterrence (specific and general), rehabilitation, and incapacitation.
- Individuals convicted of a misdemeanor serve their sentences in jail while individuals convicted of a felony serve their sentences in prison.
- With longer sentences, the inmate population is aging, and as a result more costly medical interventions will be required to meet their medical needs.
- The process of classification involves matching the level of supervision and treatment to the inmate's needs.

The structure of correctional mental health services

JOEL A. DVOSKIN, MELODY C. BROWN, JEFFREY L. METZNER, ERIN M. NELSON, AND STEVEN E. PITT

INTRODUCTION

The rate of incarceration in the United States hit alarming levels between 1978 and 2009, peaking at approximately 2,300,700 incarcerated adults in jails and prisons by the end of 2008 (Glaze 2010). Small but consistent declines in the population have been the trend since (decreases of 0.7% in 2009, 1.3% in 2011, and 0.5% in 2012; Glaze and Herberman 2013) as the number of releases from state prisons has begun to exceed the number of admissions (Carson and Golinelli 2013). Despite these decreases, the Bureau of Justice Statistics (BJS) estimates the total incarcerated population at the end of 2012 to be 2,228,400, putting approximately one in every 108 adults in the United States in prison or jail (Glaze and Herberman 2013). When compared to the global community, the United States continues to be at the top of incarcerated population rates: approximately 716 prisoners per 100,000 people versus the global average of 144 prisoners per 100,000 people (Walmsley 2013).

Commensurate with the high rates of incarceration in the United States is the high number of imprisoned individuals who suffer from a mental illness. Research indicates that a disproportionate number of inmates and detainees experience mental illness; however, prevalence estimates vary. At the conservative end of the spectrum, roughly 6%–11% of inmates in jail and prison are deemed currently in need of psychiatric care for serious mental illness, while 10%–15% require treatment for general mental illness (American Psychiatric Association [APA], Task Force on Outpatient Forensic Services 2009). Based on the 2012 estimated incarcerated population from the BJS, there were between 222,840 and 334,260 offenders with mental illness requiring treatment in U.S. prisons and jails at the year end of 2012. Teplin and Swartz (1989) noted that even after adjusting for demographic differences, the prevalence rates of schizophrenia and major affective disorder are two to three times higher in jails than in the general population. Steadman and his colleagues (1987) found that the prevalence of severe or significant psychiatric disability among sentenced felons is at least 15%. When coupled with mental retardation or brain damage, at least 25% of the inmate population in the New York State Department of Correctional Services was found to have at least a significant psychiatric or functional disability. Other studies, using vague and overly inclusive criteria, have identified more than 60% of inmates as experiencing a "mental problem" (James and Glaze 2006).

Incongruities exist when looking at the disposition and sentencing of persons incarcerated with a mental illness. Axelson and Wahl (1992) found that psychotic detainees charged with misdemeanors were discriminated against in accessing various types of pretrial release, resulting in lengths of stay six-and-a-half times longer than nonpsychotic controls. Similarly, Valdiserri et al. (1986) determined that psychotic inmates were four times more likely than nonpsychotic inmates to have been incarcerated for less serious charges such as disorderly conduct and threats. In a larger follow-up study to Axelson and Wahl's (1992), Harris and Dagadakis (2004) did not find differences in length of incarceration time between severely mentally ill and nonmentally ill control groups. They did, however, similarly find that the severely mentally ill group, who had less severe and less frequent previous offenses, was often incarcerated for the same length of time as the nonmentally ill group with more frequent and severe offenses.

In correctional institutions, those inmates with serious mental illnesses or in psychiatric crisis present a host of problems to correctional administrators. One problem, of course, is the possibility of serious injury to staff and other inmates posed by those few inmates with serious mental illness whose behavior is uncontrolled and violent. Untreated, inmates with psychoses may be terrified by hallucinations and stay up all night screaming, thereby keeping other

inmates awake, who in turn become angry and violent in response. Thus, housing assignments must take into account the mutual fears of inmates with and without mental illness.

Another problem posed by the occurrence of psychiatric crisis and severe mental illness in correctional facilities is related to liability. Suicides and restraint-related deaths may have dire legal consequences. Despite the stereotype of "guards" as tough and unfeeling, a completed suicide is often devastating to custody staff, who feel responsible for keeping inmates safe. Indeed, public opinion, so seldom sympathetic to inmates, nevertheless solidly expects correctional officials, at the very least, to keep their inmates alive. Even in the absence of adverse judgments or settlements, legal fees can be costly.

The diversity of American correctional facilities is extraordinary. Local correctional facilities range from one-person police lockups to large urban jails, which may house more than 15,000 inmates. Similarly, state prisons vary from very small field camps to prisons of more than 5000 inmates. Notwithstanding the differences between facilities, jails and prisons are alike in many ways. Both are viewed as correctional settings, with uniformed staff, secure perimeters (depending on custody level), and usually stark accommodations. Jails and prisons can also be very stressful environments, due to forced association, segregation by gender, and extremes of noise and temperature. However, the challenge of keeping their respective facilities safe is the most important similarity that jails and prisons share.

Despite such similarities, there are also important differences between jails and prisons. While prisons are self-contained environments that tend to house inmates for long periods of time, jails often hold detainees for only a matter of hours; thus, jails need to be treated as part of the larger communities in which they exist (Steadman et al. 1989). The goals of the two settings also differ. For pretrial detainees, jails exist predominantly to hold and process people until their case is resolved by the courts. Often, jail detention depends solely on external factors such as the ability of the defendant's family to raise money to post bond. For sentenced misdemeanants, jails serve as short-term (usually less than 1 year) punishment, with or without an effort at rehabilitation. Prisons, on the other hand, serve to punish the most serious offenders, and ostensibly to prepare them through various prison programs for their eventual return to society.

Over the past several decades, there have been important changes in community mental health philosophies, the most important being the Recovery Model and an emphasis on Trauma-Informed Services (Pinals and Andrade 2015; see also Substance Abuse and Mental Health Services Association [SAMHSA] 2014). The Recovery Model is a way of looking at mental illness with more hope and respect than had previously been the case. It encourages clinicians to pay attention to each person's strengths and assets instead of merely documenting pathology. It provides a more hopeful way of looking at each person's future, and encourages clinicians to help people acquire the skills that will allow them to live safely with their mental illnesses. This model is slowly being adopted by a few correctional facilities (SAMHSA 2014).

Trauma-informed care is a relatively simple but enormously important change in the way that clinicians look at the people they treat. Clinical training teaches each practitioner to ask each patient, "What is wrong with you?" Instead, a trauma-informed approach to mental health treatment asks an equally important question, "What has happened to you?" The prevalence of traumatic experiences among jail and prison inmates is well documented (Miller and Najavits 2012), and respect for these traumatic experiences can dramatically assist clinicians informing a therapeutic alliance with their clients.

Needless to say, the difficult and stressful correctional environment creates serious challenges to the formation of the therapeutic milieu or relationship (Pinals and Andrade 2015). Nevertheless, correctional mental health workers who understand these principles can provide a higher quality of service to their clients and to the institutions in which they work.

THE LEGAL REQUIREMENTS FOR CORRECTIONAL MENTAL HEALTH SERVICES

O'Leary (1989), Cohen and Dvoskin (1992), Cohen (1988, 1998), and Jones (2015) have written extensively about the legal bases for requiring mental health services in jails and prisons, in addition to the required components and standards that various courts have established for such services.

Pretrial detainees have a due process right not to be punished, while convicted inmates are prohibited from suffering cruel and unusual punishment. For pretrial detainees, the right to treatment stems from due process rights guaranteed by the Fourteenth Amendment. "Detainees are entitled to at least the same level of care as the convicted" (Cohen, 1998, pp. 2–14). A convicted inmate's right to medical and psychiatric treatment in prison, guaranteed by the Eighth Amendment, stems from the state's role as incarcerator. In *Estelle v. Gamble* (1976), the Supreme Court interpreted this responsibility as the duty to avoid "deliberate indifference" to the serious medical needs of inmates. Other federal and state courts specifically included psychiatric needs within the standard (e.g., *Bowring v. Godwin* 1977), and have required that treatment be greater than the provision of psychotropic medication (*Langley v. Coughlin* 1989). It was not until 1994, however, with *Farmer v. Brennan* (1994), that a clearer definition of this term was presented. The *Farmer* decision equated deliberate indifference with recklessness, and applied the criminal standard of "actual knowledge" of risk. It is not essential to prove that an official clearly believed that harm was imminent; only that an official possessed substantial knowledge of risk (Cohen 1998). Examples of the application of this standard can be found in cases such as *Coleman v. Wilson* (1995) and *Madrid v. Gomez* (1995), both of which speak to the necessity of providing adequate treatment to inmates with mental illness.

To incarcerate someone with deliberate indifference to his or her significant psychiatric needs is thus viewed as cruel and unusual punishment and may be remedied, often through class action lawsuits, by injunctive relief, or by compensatory and/or punitive monetary damages. The conservative turn in the federal judiciary, however, has made it far more difficult for plaintiffs to succeed in such actions (e.g., *Wilson v. Seiter* 1991; *Hudson v. McMillan* 1992).

Congress has also been conservative relevant to prison reform, as reflected in passage of the *Prison Litigation Reform Act* (PLRA; 1996). The PLRA established new procedural requirements for suits by prisoners and significantly limited the ability of the courts to order relief. Consent decrees now require a finding of unconstitutional conditions (i.e., admission of such conditions by the defendants), fees are limited for special masters and attorneys, and other restraints to remedies are present. The U.S. Supreme Court in *Miller et al. v. French et al.* (No. 99–224, decided June 19, 2000) upheld the constitutionality of this act that had been challenged on due process and separation of powers principles.

In addition to constitutional litigation, correctional administrators who ignore the mental health needs of at-risk inmates who go on to commit suicide may also be vulnerable to tort liability, such as wrongful death actions (O'Leary 1989). Injuries to staff and other inmates resulting from inadequate mental health services can also lead to tort liability, as well as great expense due to occupational injury leave and disability retirements. In addition, inadequate medical or psychiatric services can result in malpractice claims against both medical and mental health providers in the jail.

Evolving legal requirements

Lower courts, generally via class action litigation, have also dealt with specific programmatic aspects of correctional mental health systems that include the placement of inmates with a serious mental illness in long-term segregation housing units, discharge planning, and the quality improvement process.

Because it is common for inmates with a mental illness to be overrepresented in segregation housing units, especially in systems that have problematic or inadequate mental health services, courts have attempted to partially remedy this problem by requiring mental health screening during the time immediately surrounding transfer of inmates to such housing units and/or establishing a process for providing mental health input into the disciplinary process (*Coleman v. Wilson* 1995). The purposes of the screening process include triaging of an inmate's mental health needs and exclusion of inmates from segregation housing when clinically indicated (e.g., due to psychosis or significant suicide risk). Courts have also required ongoing "rounds" in segregation housing to provide ongoing assessment of segregated inmates (*Coleman v. Wilson* 1995).

Courts have also required that inmates with a serious mental illness housed in segregation units must have access to appropriate levels of mental health treatment based on their clinical needs (*Madrid v. Gomez* 1995; *Ind. Prot. & Advocacy Servs. Comm'n v. Comm'r, Ind. Dep't of Corr.* 2012). Such treatment should include both structured out-of-cell therapeutic programming and unstructured out-of-cell recreational time. For example, for inmates requiring a special needs level of mental health care (e.g., residential level of care), at least 10 hours per week of structured therapeutic activities and another 10 hours per week of unstructured recreational time have been recommended by Metzner and Dvoskin (2006).

Mental health input into the disciplinary process for inmates with a serious mental illness has also been a component of remedial plans designed to reduce the length of stays for inmates with a serious mental illness in locked down settings (*Disability Advocates, Inc. v. New York State Office of Mental Health* 2007). Mental health assessments are designed to answer the question of whether the inmate's rule infraction was related to symptoms of a mental illness and, if so, whether the disposition should be mitigated (e.g., reduced disciplinary housing time) by the hearing officer.

Discharge planning has been increasingly recognized by both mental health and correctional staffs to be an essential element of an adequate correctional mental health system related to both the obvious clinical purposes and due to the benefits from a perceived reduced recidivism rate. Although decided on the basis of state statute and case law, *Brad H. v. City of New York* (2000) is instructive regarding the risks from a legal perspective of not providing adequate discharge services. A settlement agreement was reached in which the city is to provide discharge planning services that include, depending on clinical indications, medications, assistance with housing and entitlements as well as linkage services.

Grubbs v. Bradley (1993), *Coleman v. Wilson* (1995). and *Madrid v. Gomez* (1995) emphasized the importance of a quality assurance/improvement (QI) process in remedying an inadequate correctional mental health system. A QI system has been increasingly recognized within the correctional health-care field as an essential component in order to continually improve the effectiveness and quality of health-care services provided.

DIVERSION PROGRAMS

There are a number of reasons why people with mental illness find their way into correctional settings despite efforts to divert them to alternative dispositions (Lamb and Weinberger 1998). For some, the offense will be severe and unrelated to their mental illness, thus ruling out the possibility of dismissing charges or negotiated insanity pleas. For others, coincidental onset of a serious mental illness, often exacerbated by the stress of their incarceration and the correctional environment may result in decompensation in some individuals who were mentally intact prior to their incarceration (Gibbs 1987; Muzekari et al. 1999). Finally, with the continuously high rate of illegal drug use and its well-documented relationship to criminal behavior

(see, e.g., Petrich 1976; Mirsky 1988; O'Neil and Wish 1990; Office of National Drug Control Policy 2013), urban jails face high numbers of newly admitted inmates who suffer from drug-induced psychosis on arrest.

Diversion programs are essentially intended to shift offenders with mental illness and/or substance abuse problems away from the criminal justice system (The Center for Health and Justice at TASC 2013). This does not imply, however, that mentally ill offenders should not, or would not, ever be detained. Although diversion may prevent incarceration in some cases, it may also mitigate the time spent behind bars, as well as impose contingencies for aftercare upon release. For those offenders requiring detention, mental health services must be provided by the correctional facility. Generally speaking, however, nonviolent mentally ill offenders are not likely to have their ongoing mental health needs best met by serving jail time. Instead, the safety of the community is better served by providing a comprehensive, inclusive diversion program designed to meet the needs of the offender, as well as the mental health and criminal justice systems (Coleman 1998; GAINS Center for Behavioral Health and Justice Transformation [GAINS] 2010).

Mental health courts (MHCs) are a relatively recent development to further assist in diverting offenders with mental illness and/or substance abuse problems. Initially funded by an act of congress, America's Law Enforcement and Mental Health Project (2000), MHCs typically handle nonviolent offenders, diagnosed with a mental illness or a co-occurring diagnosis of mental illness and substance abuse, who agree to the terms of enrollment in the program. They are intended to coordinate all violations, mandated treatment, and connecting the offender with social services in the community, including employment, housing, education, health care, and relapse prevention (American's Law Enforcement and Mental Health Project 2000). Research has largely shown that MHCs are working to reduce recidivism (Moore and Hiday 2006; McNiel and Binder 2007; Hiday and Ray 2010; Hiday et al. 2013) and to connect mentally ill patients with needed treatment in their communities (Steadman et al. 2011). The largest and most comprehensive study to date has been the on-going, multi-site MacArthur Foundation study (Steadman et al. 2011). Results from this study have confirmed a reduction in recidivism rates for those who participated in the MHCs system and also found a shift from crisis treatments to intensive treatments as compared to the control group (Callahan and Wales 2013). These findings indicate that MHCs appear to be working to both reduce recidivism as well as to effectively link offenders with community-based treatments.

Despite widespread agreement about the need for effective jail diversion programs, existing programs share few similarities. Since their implementation in 1992, diversion programs have grown substantially in number, with more than 560 programs existing across 47 states (GAINS 2010). With many varieties of resources and leadership, as well as differing needs of each community, it is not surprising to find significant variations in program models used (Clark 2004). Subsequent disparate definitions of inclusion criteria, strategies, and objectives have resulted in limited meaningful data available to evaluate existing programs and/or to provide guidelines for the continued development of future programs (Steadman et al. 1994a,b, 1995; Draine and Solomon 1999). Steadman and Naples' (2005) multisite evaluation, the largest to date, determined that there is growing evidence in support of jail diversion programs as beneficial to individuals, systems, and the communities they serve. In conjunction with ongoing research regarding the effectiveness of jail diversion programs (see also Steadman et al. 1994a,b), Steadman et al. (1995, 1999) delineated six key elements common to the most successful programs. First, effective programs included interagency involvement (e.g., mental health, substance abuse, and criminal justice systems) beginning at the program's inception. Second, regularly scheduled interdisciplinary communication between representatives was built in to the structure. Third, service integration was orchestrated by a designated "boundary spanner" who served as a liaison between agencies. A fourth key element was the presence of strong leadership. The fifth key element was the early identification of detainees with mental illnesses who meet the criteria for a diversion program. Finally, effective diversion programs consistently employed nontraditional case management strategies.

Whether diversion occurs pre- or post-booking, "the best programs see detainees as citizens of the community who require a broad array of services, including mental health and substance abuse treatment, housing and social services" (APA 2000, 29). Program success has essentially depended on building new system linkages and holding the community responsible for the provision of services (Steadman et al. 1999). Policies providing for the selective diversion of specific mentally ill offenders, and/or their careful reintegration into the community following incarceration, are more desirable than existing alternatives (Cohen 1998). In sum, the development of comprehensive diversion programs may break the "unproductive cycle of decompensation, disturbance, and arrest" (APA 2000, 30) so familiar to many of our nation's citizens with serious mental illnesses.

SERVICE COMPONENTS OF CORRECTIONAL MENTAL HEALTH CARE

Due to the many differences between jails and prisons, the priorities for mental health services are somewhat different in each setting. For example, Steadman (1990) found that for jails, the priority services are screening, crisis intervention, and discharge-oriented case management. Prison environments, on the other hand, due to their typically longer lengths of stay, lend themselves to the possibility of longer-term psychotherapy and psychiatric rehabilitation rarely seen in jails. Despite these differences, the services themselves fall into generic categories that hold up rather well across the two settings. Nevertheless, it is important to

be mindful of the inevitable differences, subtle or obvious, between the implementation of services, as they are adapted to each specific correctional environment.

Perhaps the most comprehensive description of essential correctional mental health programs can be found in the APA's Work Group Report on Psychiatric Services in Correctional Facilities (APA 2015).

Cohen (1998) lists six minimal essential elements underlying the service components, taken from a prison class action suit in Texas (*Ruiz v. Estelle* 1980), as providing a useful framework for planning mental health services (see also APA 1989, 2000, 2015; Hills et al. 2004):

1. Systematic screening and evaluation
2. Treatment that is more than mere seclusion or close supervision
3. Participation by trained mental health professionals
4. Accurate, complete, and confidential records
5. Safeguards against psychotropic medication prescribed in dangerous amounts, without adequate supervision, or otherwise inappropriately administered
6. A suicide prevention program

In addition, a quality improvement process has become an essential component of most remedial plans or Settlement Agreements during the past decade (Metzner 2012).

Screening

Screening is regarded as perhaps the most important service element in correctional mental health (Pogrebin 1985; Teplin and Swartz 1989; Maloney et al. 2015). Screening is not only a specifically required legal obligation (Cohen 1998) but is clinically and programmatically essential. It is impossible to appropriately treat inmates with serious mental illnesses or psychiatric crises without identifying the specific individuals affected. The APA's Work Group Report on Psychiatric Services in Correctional Facilities (2016) lists four levels of mental health screening and evaluation procedures to be conducted as soon as possible after intake:

> *(Receiving mental health) screening includes observation and structured inquiry into mental health history and symptoms, including questions about suicide history, ideation, and potential; prior psychiatric hospitalizations and treatment; and current and past medications, both prescribed and what is actually being taken….*
>
> *Intake mental health screening is defined as a more comprehensive examination of each newly admitted inmate within 14 days of arrival at an institution. It includes a review of the reception mental health screening, medical screening, behavioral observation, review of mental health history, assessment of suicide potential, and mental status examination….*
>
> A brief mental health assessment is defined as a mental health examination appropriate to the level of services needed…. Brief mental health assessments occur within 72 hours of a positive screening and a referral (in an office with sound privacy.) Urgent cases receive immediate evaluation after referral….
>
> *A comprehensive mental health evaluation consists of a face-to-face interview in an office with sound privacy and a review of available health care records and collateral information. It concludes with a diagnostic formulation and, at least, an initial treatment plan.*

The National Commission on Correctional Health Care (NCCHC 2014a,b) recommends similar procedures, with a brief mental health assessment and/or a comprehensive mental health evaluation being required only if positive results occur. Maloney et al. (2015) estimate a typical positive referral rate of 25%–33% for further assessment beyond the initial intake assessment. Although there are a number of acceptable ways to provide this screening, several specific elements must be present:

- *Trained staff.* Standardized screening tools can be successfully administered by line staff, nurses, or case managers, provided that they are adequately trained in the administration of each screening instrument and know where to refer inmates in need of services.
- *Documentation.* The results of the screening must be clearly and legibly documented and available to those responsible for medical care, housing assignment, and follow-up services. Records must be maintained in a manner that assures the privacy and confidentiality of each inmate, while facilitating communication between different mental health and medical providers.
- *Low threshold.* The screening must have a low threshold for referral for more extensive evaluation. That is, any indication of either a history or current evidence of mental illness or psychiatric problems must result in referral for a follow-up evaluation. Likewise, any unusual or eccentric mannerisms or behaviors observed must be specifically documented and referred for further evaluation.
- *Standardization.* By routinely utilizing a standardized screening process during booking and by training staff in the screening procedure, one avoids an idiosyncratic process where a mentally ill inmate's chances of being identified depend on who happens to be on duty when the inmate arrives.

Martin et al. (2013) and Gebbie et al. (2008) provide comprehensive reviews of multiple screening tools available for correctional facilities. Ford et al. (2007) suggest that screening instruments should be brief; contain clear definitions, thresholds, and criteria; have low false-negative rates; and have reasonable false-positive rates. Based on these elements, Maloney et al. (2015) recommend four specific

scales as effective screening devices: variants of the New York instrument, a suicide prevention screening guidelines form developed by agencies in New York (Sherman and Morschauser 1989); the Brief Jail Mental Health Screen (Steadman et al. 2005) used in conjunction with the New York instrument or other suicide screening instruments; the Correctional Mental Health Screen (Ford et al. 2007); and "15 Questions," a screening instrument used in the Los Angeles County Sheriff's Jail system.

Follow-up evaluations

No matter who conducts screening for mental health service needs, it will be necessary to provide more extensive and detailed evaluations for those inmates identified as potentially in need of mental health services. These examinations must be timely and responsive to specific issues raised during the screening, and must result in treatment recommendations that are practical within the correctional setting.

Because psychiatrists are difficult to recruit and are a great deal more expensive than other mental health providers, it makes sense to have these "second-level" follow-up evaluations routinely conducted by psychologists, social workers, or psychiatric nurses with advanced degrees. However, as these evaluations will be primarily diagnostic in nature, they will optimally be conducted by at least master's-level staff (preferably licensed) with training in psychopathology (Dvoskin 1989).

It is important to limit these evaluations to issues that have immediate and feasible treatment implications. Given the generally limited treatment resources in correctional settings, full-scale psychological test batteries should be limited to inmates whose symptoms raise diagnostic questions that can only or best be answered by psychological testing (Dvoskin 1989). For inmates who appear to require psychiatric services such as psychotropic medication, a referral to a psychiatrist or licensed independent provider (e.g., Advanced Practice Nurse Practitioner) will then be in order. Of course, in cases where a detainee enters the jail with psychotropic medication, or a long history of such treatment, it may be cost-effective to bypass this step and have the person referred directly to a psychiatrist.

It is important to have some capacity for the emergency administration of medication during weekends and nights. On-call psychiatrists may provide telephone consultation with on-site nonpsychiatric physicians, registered nurses, or physician's assistants. Twenty-four-hour on-site psychiatric availability is a luxury likely to be found only in a few very large and well-funded settings. In smaller jurisdictions, mobile crisis teams from the local community mental health provider or nearby general hospital emergency rooms may be able to provide services at the jail.

Psychotropic medications

Psychiatrists who work in correctional settings must be aware of all of the usual issues surrounding emergency psychiatry (e.g., Anderson et al. 1976; Salzman et al. 1986; Dubin 1988; Allen 2002). There are several other considerations that are especially or even uniquely important in dealing with inmates who are being treated for a psychiatric condition. People who are put in jails or prisons have often failed or refused to take their psychotropic medications as prescribed. It should therefore not be surprising that inmates may be unwilling to take their medication exactly as ordered by physicians (Smith 1989). Inmates who feel oppressed by the criminal justice system sometimes view psychotropic medication ordered by an institutional physician as an instrument of that oppression. Other inmates, believing the correctional environment to be unsafe, prefer to remain as alert as possible, and decline to take medications that are designed to provide tranquilization. Alternately, it is possible that inmates who are not suffering from a mental disorder may seek psychotropic medication in hopes of alleviating some of the situational stresses associated with their incarceration, or in hopes of selling them for profit.

Limitations in psychiatric resources are a significant issue in the provision of psychotropic medications to inmates. Busy physicians may spend an inadequate amount of time explaining the need for medication, its value to the inmates, or what to do about side effects. It takes time to build trust and create a truly therapeutic relationship between psychiatric providers and their patients, and shortages of clinical staff often make it difficult to do so. Moreover, systemic constraints on the flow of information may create protracted time periods between an inmate's initial complaint of side effects and his or her appointment with a physician.

Case management

Active case management is invaluable, yet frequently underutilized, in correctional mental health care. Case managers benefit inmates during their period of incarceration, as well as serve an essential role in the discharge planning process. For inmates who are confused and anxious, regular and surprisingly brief visits can provide reassurance that the inmate has not been psychologically abandoned. Often, the simple provision of accurate information about the criminal justice process can relieve a tremendous amount of anxiety and need not always be supplied by mental health professionals.

Within the correctional setting, stressors may build up in the absence of supportive services. It therefore is important periodically to "check in" with identified psychologically vulnerable and mentally ill inmates even during periods of apparently good adjustment. The establishment of a tracking mechanism identifying those inmates who are not receiving active mental health services, yet have a history of mental illness, can be of great benefit toward the maintenance of the inmate's psychological fitness. Case managers are ideal providers of such a service. Even annual visits with a case manager will allow the inmate a sense of connectedness and security, while simultaneously providing the

mental health department with an opportunity to monitor the inmate's status. These very brief contacts are a worthwhile investment, especially if they prevent more serious exacerbations of an inmate's condition, thereby forestalling more extensive and costly services. Therefore, the inclusion of case management services offers the facility a prophylactic tool, reducing financial burden as well as mediating the potential for crises that disrupt normal facility functioning.

Case management is even more effective in linking inmates to appropriate mental health services on their release (Griffin 1990). Prior to discharge, case managers can play an integral role in the building or nurturing of social supports, such as helping the inmate to contact family or friends. Such collateral contact can be particularly helpful toward improving an inmate's quality of life while incarcerated as well as upon return to the community (Jacoby and Kozie-Peak 1997). Perhaps most importantly, however, case managers serve as a bridge, linking inmates with providers in the community. Continuity of care is critical to appropriate mental health service and falls well within the venue of case management service. Even the most impressive correctional mental health-care program can be rendered futile if the inmate patient is not linked with appropriate services after discharge (Steadman et al. 1995). Lamb and Weinberger (1998) assert that appropriate implementation of mental health services (and use of case managers) "would mean tailoring mental health services to meet the needs of mentally ill offenders and not treating them as if they were compliant, cooperative, and in need of minimum controls." Unfortunately, the criminal justice system is largely unprepared to provide case management services to mentally ill offenders upon release (Lamb and Weinberger 1998), and if not carefully monitored and adjusted, the patient may experience a variety of unsettling, uncomfortable, and even dangerous side effects. As a result, correctional nurses need to take special care when administering medications in the jail to ensure that the inmates are not "cheeking" medications to appear compliant or to save for later sale. Minor tranquilizers are especially prone to abuse and black market sale within the jail, and therefore are often not included in correctional formularies.

Crisis intervention

In the correctional setting, psychiatric crises may arise at any time, and involve virtually any offender. Crisis services must be readily accessible at all points during the intake and incarceration process. Even where the very best screening and evaluation services are present, it will still be impossible to identify on admission all of the inmates who will require psychiatric services during their incarceration or detention. No screen is perfect, and even "cutting-edge" instruments will have some false-negative errors. Further, certain kinds of psychoses may allow the inmate to appear, at least temporarily, quite unimpaired even under stress. It is important to note, however, that there are a number of reasons why inmates will either be, or appear to be, psychologically intact upon intake, and later experience a psychiatric crisis within the jail setting.

Jails and prisons can be extraordinarily stressful environments. Overcrowding, extremes of cold or heat, noise, filth, and the fear of assault may all contribute to the psychological deterioration of even the most "mentally healthy" inmate. Jails may be even more distressing than prisons, because most jail inmates have recently arrived and have a great deal of uncertainty as to the outcome of their legal status. For first-time offenders especially, their expectations are likely to be colored by television or movie dramatizations stressing violence in jails. Perhaps most upsetting to first-time offenders is the simple truth that jail inmates are not always very nice to one another. Together, these various stressors can lead to psychiatric decompensation at any time during the course of incarceration.

Another risk factor is any pre-existing psychological condition that makes a person vulnerable to psychiatric crisis or mental illness. Family histories of an affective disorder appear to increase the risk of severe depression, which could be triggered by the stresses associated with incarceration. Certain personality disorders, especially borderline personality disorder, create a variety of risks for psychiatric crises, including suicide gestures, emotional hyper-reactivity, and acute psychoses, especially in response to being locked up (Metzner et al. 1998).

Administration of psychotropic medications in emergency situations can be dangerous, especially with newly admitted inmates whose urine and serum blood toxicology results are pending. As the incidence of illegal drug abuse has increased, the likelihood of a psychiatric crisis being due to illicit drug use has also increased. The safe prescription of medications in emergencies involving newly admitted inmates should thus include a physical examination. Since the time of day will often preclude such safeguards, many physicians will elect such nonpharmacological treatment interventions as constant observation to resolve the immediate crisis and keep the inmate safe until services can be obtained. Other facilities will elect to utilize local general hospital emergency rooms.

Every jail and police lockup that receives direct admissions from the street must have access to medically supervised alcohol and drug detoxification services. However, this detoxification is primarily medical in nature and is not a mental health service. Once detoxification has been safely accomplished, mental health staff should provide assessment of any needed mental health services. For inmates with both mental illness and substance use disorders, upon release there should be a referral to a community program that provides for integrated treatment of co-occurring mental illness and substance use disorders.

Consultation services, when provided by mental health staff to correctional staff, can vary extensively, from sophisticated suggestions for handling difficult inmates to simply suggesting a cell change. The mental health staff must be viewed as supportive of the correctional staff's mission to make the facility safe for everyone.

Special management precautions in response to psychiatric emergencies include moving the inmate to a different bed location, thereby separating violent inmates from others, possibly allowing for easier and more frequent observation or closer proximity to nursing or other services. Often inmates will be put on "special watches" such as constant observation or one-to-one, especially where suicidal intent is suspected.

The special management precautions are required for two reasons. Each facility has an overriding obligation to protect inmates or detainees from foreseeable and preventable harm. There is also a duty to provide medical or psychiatric treatment, although the two considerations will often overlap. In either case, the most important job in any correctional psychiatric crisis is to ensure the safety of all of the people who live and work there. Thus, crisis response is as much the responsibility of correctional staff as it is the mental health staff, even where 24-hour mental health staff are available.

Verbal counseling in crises is not only the least intrusive intervention available, but often it is the most effective—especially when the crisis is in response to a specific event or the novelty of the incarceration itself. For any inmate, with or without long-standing mental illnesses, these crises are often a response to fear. Inmates fear many things, some real and some imagined. Often, simply providing information, spiking rumors, or offering support can significantly improve an inmate's response to his or her situation.

As with nearly all jail-based mental health services, it is imperative that adequate documentation and communication of crisis responses be maintained. When off-hour providers are contractors or are from other agencies, it is imperative that essential aspects of the crisis and actions taken in response to it be communicated to the mental health, medical, and correctional staff. Likewise, facility correctional and medical staff should, as standard policy, have a mechanism in place by which they can alert mental health staff of concerns about a given inmate. For instance, a third-shift officer might observe idiosyncratic behavior and should have a routine method of documenting his or her observations and informing the mental health department.

Finally, the competent resolution of any crisis must include some reasonable effort to prevent its recurrence. While the provision of information itself can be effective, other steps may include supporting a psychologically fragile inmate through a crisis, or preventive steps such as ongoing supportive therapy or skill building (e.g., how to safely "do time").

Thus, correctional facilities, as a matter of law and sensible policy, must have some sort of ready access to crisis services. These services include psychotropic medication, special watch procedures, psychological or counseling services, detoxification (because drugs may be available inside the facility), information (such as when the inmate will get to see a lawyer or receive visits), and consultation with correctional staff about how to handle problematic inmates.

Suicide prevention

Although suicide is clearly one of many sources of potential crisis in the correctional setting, its impact demands special consideration. Suicides in jails and prisons are often preventable, and jail suicide rates are especially likely to exceed general population rates in the community. The likelihood of higher rates is especially great if a suicide prevention program is not established. Standards for suicide prevention programs or protocols did not, however, begin to formalize and adequately address suicide prevention until the mid to late 1980s (Hayes 1995). The NCCHC (2014a,b) currently provides standards required for suicide prevention programs to follow, in order to maintain accreditation, with the following key components:

- *Training* should be provided for all staff to recognize verbal and behavioral cues that indicate potential suicide.
- *Identification* of ongoing risk should be made through routine and continuous risk assessments, especially at intake.
- *Referral* procedures should be specified, for suicidal inmates, to mental health-care providers or facilities.
- *Evaluation* should be conducted by a qualified mental health professional to determine risk level and the need for treatment of underlying mental illnesses.
- *Treatment* should address the underlying reasons for the inmate's suicidality.
- *Housing* should be safe and as suicide resistant as possible, with special attention to potential anchoring devices such as door hinges/knobs, air vents, and window frames; suicidal inmates should also not be placed in isolation unless constant supervision can be maintained
- *Monitoring* should be conducted at three levels based on status of risk: constant observation, with 1:1 monitoring; intermediate observation at intervals no longer than 5 minutes; and close observation in staggered intervals no longer than 15 minutes
- *Communication* should be ongoing between arresting/transporting officers, correctional staff, facility staff (including medical and mental health staff), and the at-risk individual for any signs or behaviors that may indicate a risk for suicide.
- *Intervention* procedures should address how to handle a suicide in progress, including how to cut down a hanging victim and other first-aid measures.
- *Notification* procedures should be in place for notifying prison administrators, outside authorities, and family members of potential, attempted, or completed suicides.
- *Reporting* procedures should be followed for documentation of the identification and monitoring of potential or attempted suicides.
- *Review* procedures for medical and administrative review in the event a suicide does occur.

- *Debriefing* provides individuals with an opportunity to discuss their thoughts and feelings about an incident.

Especially in local correctional facilities, where suicide rates are typically higher, suicide prevention has received a great deal of attention over the past few decades (Atlas 1989; Cox and Landsberg 1989; Cox et al. 1989; Haycock 1989; Hayes 1989; O'Leary 1989; Rakis and Monroe 1989; Sherman and Morschauser 1989). The combination of increased awareness of the problem and changes in institutional policy and practice have reduced the rates of suicide in jails and prisons by more than half since 1983 (Hanson 2010; Hayes 2012). According to the BJS, jail suicide rates dropped to their lowest in 2007 at 36 per 100,000 detainees but have increased slightly since to 43 per 100,000 in 2011 (Noonan and Ginder 2013). The suicide rate in prisons has remained fairly consistent between 2001 and 2011 at a rate of 14 per 100,000 prisoners, which is only slightly higher than the suicide rate for the general population (Noonan and Ginder 2013).

A comprehensive statewide program in New York enabled sheriff and police departments to dramatically reduce jail suicides (Cox et al. 1989) and has since been replicated in jails across the country. Applying a public health model to suicide prevention, this state-funded program is a simple and locally implemented scheme of staff training and procedure development for identifying and managing inmates at high risk of suicide, and is described in greater detail in Chapter 56.

As suicide rates have decreased, other trends and challenges have emerged that will require increased awareness and a potential change in protocols. One such trend is the increase in length of time of confinement before suicide occurs. Previously, research indicated that more than 50% of victims had died in the first 24 hours of confinement (Hayes 1983, 1989). The current trend reflects a much larger range: anywhere from 2 days to 4 months of confinement (Hayes 2012). This change is encouraging, in that it demonstrates the effectiveness of initial screening and prevention efforts; however, it also means that correctional staff need to remain vigilant and aware of potential suicidal indicators for a much longer period of time. Nevertheless, the first 72 hours of incarceration remain the focus of attention, especially since these typically include hours during the evenings or weekends when no clinical professionals are present. Suicide prevention also demands consistent staff emphasis on assessments by qualified mental health professionals and taking necessary precautions in handling patients with increased risks of self-harm (Hayes 2012).

As will be discussed in a subsequent section, active training and involvement of correctional staff is an essential component of correctional mental health. This tenet is especially true of suicide prevention. All staff, administrative and/or security, that have contact with inmates should undergo specific training in suicide risk assessment and intervention. Although the most common recourse for correctional staff will be to alert mental health personnel about an at-risk inmate, it is vital that they are at least cognizant of both risk factors and intervention strategies in the event that they become involved in a suicidal crisis situation. Laypersons without mental health training may harbor false beliefs regarding suicide potential. For example, many people wrongly believe that a person who is truly suicidal would never talk about it. Dispelling myths about suicide, and adopting an all-inclusive training policy for correctional personnel, can have a substantial impact on the psychological well-being of staff and inmates alike.

In addition to screening, essential aspects of a suicide prevention program include (1) clear policies and procedures governing the actions of all staff, including health care, mental health care, and custody staff; (2) an interdisciplinary suicide prevention committee; (3) investigation and quality improvement analysis of all serious attempts and completed suicides; and (4) assurance that all suicide watches are accomplished in a diligent and timely manner.

External hospitalization

Although access to hospitalization for emergency psychiatric treatment is essential, it is often unavailable, especially to smaller jails. The ability to obtain brief psychiatric inpatient care when necessary is of tremendous importance not only to the inmate requiring the transfer but also to the other inmates and staff. The goal of emergency hospitalization is to reduce severe psychiatric symptoms and stabilize the patient. Follow-up treatment should continue either in the correctional facility or, if pretrial release can be obtained, in the community.

Jails often use inpatient hospitals by transferring the detainee to an outside psychiatric hospital or ward. However, some jurisdictions such as San Diego, California (Meloy 1985), Los Angeles County, and Westchester County, New York, provide inpatient treatment within the local jail itself. Prison systems may house psychiatric inmates (who are unable to function adequately in the general population) at an off-site correctional facility whose purpose is to provide inpatient psychiatric care. Such facilities are staffed with correctional officers specially trained in mental health issues or psychiatric technicians with some correctional or security training. Regardless of context or locale, both jail and prison systems must have access to inpatient psychiatric services ranging from brief crisis intervention to longer-term psychiatric hospitalization.

Telemedicine

Telemedicine is essentially the transmission of electronic information, such as voice data and teleimages across geographically distant communication facilities, thereby allowing for long-distance patient health care and/or diagnosis (Charles 2000). Telemedicine has been used to enhance treatment options for geographically remote patients for almost six decades (Stevens et al. 1999). More recently, however, the rising cost of health care, including mental health

care, and the increasing difficulty in recruiting and retaining psychiatrists have generated heightened interest in telemedicine and its promise of increased accessibility coupled with decreased cost. Technological advances (Mair and Whitten 2000) and decreasing implementation expenses (Strode et al. 1999) have enhanced the appeal of telecommunication as a viable alternate treatment modality.

Complications surrounding geographic isolation and limited access to mental health professionals familiar with the correctional setting may, at times, compromise care for inmates (Magaletta et al. 1998). In the correctional setting, access to any extra-institutional health-care service (psychiatric or otherwise) often requires extraordinary transportation and security expenses. Through telemedicine, correctional facilities, frequently located in remote areas, can minimize costly inmate transport, while concurrently allowing even the most dangerous inmates access to services in a secure environment (Charles 2000). Additionally, when telemedicine allows an inmate more timely access to psychiatric care, the likelihood of agitation and volatility may be reduced, thereby creating a more secure institutional environment for all correctional staff and inmates (Magaletta et al. 1998).

Stevens et al. (1999) reported that nonincarcerated patients and their treating psychiatrists were able to develop rapport via televideo just as well as when they were in the same room. Similarly, Morgan et al. (2008) found no differences in treatment satisfaction or inmates' perceptions of the therapeutic relationship when comparing a group receiving only tele-mental health to a control group receiving psychiatric services face to face. Further, preliminary data from the Federal Bureau of Prisons (BOP) telehealth pilot program indicated that virtually all inmate–patient participants, as well as treating psychologists and psychiatrists, have expressed satisfaction with telehealth services (Magaletta et al. 1998). The BOP telemedicine and telepsychiatry programs have been successful to such an extent that the Bureau is in the process of implementing telehealth technology system-wide (I. Grossman, personal communication, August 29, 2000). As of 2004, telemedicine and telehealth programs were operating in about half of all state correctional institutions and approximately 39% of federal institutions in the United States (Larsen et al. 2004). The Texas Department of Criminal Justice, Institutional Division, in conjunction with the University of Texas Medical Branch (UTMB) and Texas Tech University Correctional Managed Care organizations, has likewise enjoyed a successful telemedicine program. The UTMB region telepsychiatry division alone serves over 200 inmates per month and has received overwhelmingly positive responses from inmates and psychiatrists alike (R. Stanfield, personal communication, August 23, 2000; P. Nathan, personal communication, September 7, 2000).

Discharge planning

Discharge planning, also known as transition or reentry planning (American Association of Community Psychiatrists 2001), has become an important topic in the past decade as a result of several class-action lawsuits in correctional systems. A settlement was reached in 2003, as part of the *Brad H. v. The City of New* York (2000) class-action lawsuit, which specifically outlined appropriate steps for discharge planning for mentally ill inmates. Several states have expanded upon those requirements to include issues such as general health concerns (see *Foster v. Fulton County, Georgia* 2002) as well as drug and alcohol rehabilitation (see *United States of America v. Nassau County* 2001). Both the NCCHC and the APA also discuss the importance of adequate discharge planning and provide standards of care.

The logistics of implementing adequate procedures can be different for jails versus prisons due to differences in the lengths of stay as well as the unpredictability of discharge dates. For example, high turnover rates and shorter stays in jails require mental health professionals to begin discharge planning as soon as offenders are admitted (Dvoskin and Brown 2015). Although a great deal of variance exists between facility practices and policies, the primary purpose of any discharge planning procedure is to provide necessary and adequate resources in order for prisoners or detainees to safely return to the community. Discharge planning should begin as soon as a prisoner or detainee is identified as mentally ill, and continue throughout his or her stay. La Vigne et al. (2008) identified eight essential elements for discharge procedures:

- *Transportation* should be provided upon release to their destination as well as arrangements to ensure access to other locations mandated in their release plan, including transportation to obtain necessary medications.
- *Clothing, food, and amenities* should be provided or discussed, including clean and seasonally appropriate clothing and information for accessing food resources in the community.
- *Financial resources* should be provided to cover bare necessities including subsidized food, transportation, and shelter for the first several days after release.
- *Documentation* should be confirmed or provided in the form of a state-issued identification card.
- *Housing* should be identified that is safe and affordable for the first several days after release, and it should be confirmed that bed space is available prior to release.
- *Employment and education* assessments and referrals should be completed to assist the person in finding and maintaining employment.
- *Health care* facility/provider information in the community should be provided after an assessment of the person's mental and physical health-care status and needs in order to ensure continuity of care, and the person should be provided with enough medications to last until he or she can be seen by a health-care professional in the community; individuals with substance abuse or mental health issues should also have appointments scheduled with counselors in the community prior to release.

- *Support systems*, including family members and/or community- or faith-based organizations, should be provided with the offender's release date and plan in order to provide support after release, and a handbook listing community resources should also be provided.

Despite the best efforts of staff, many challenges still exist in transitioning offenders successfully and safely back into the community. A lack of funding and community resources is a common problem that can significantly affect the ability for released inmates to have their needs met (La Vigne et al. 2008). Another challenge is getting the cooperation and compliance of the offender, which can become more difficult when the offender's ability to manage his or her affairs has deteriorated after adjusting to life in confinement (Nelson and Trone 2000). Especially important is connecting inmates with entitlement programs such as Medicaid that can provide health care for indigent offenders after they are released, at least until they can gain access to employment and health insurance.

PSYCHOLOGICAL THERAPIES

Individual therapy

Environmental pressures inherent to the correctional setting can engender mental distress (Lindquist and Lindquist 1997). Even the most mentally healthy inmates may periodically find themselves in need of psychological services while incarcerated. Often, brief therapeutic contact is sufficient to alleviate situational stresses and transient difficulties encountered in the correctional setting. As previously discussed, case managers or social workers can be an invaluable resource for inmates in need of emotional support, information, or assistance with negotiating the daily demands of incarceration. In fact, the type of "therapy" most valuable to jail inmates is often provided by staff who lack formal training but who have a natural ability simply to treat others with dignity and humanity. Often, jail and prison inmates report that they were most helped through a crisis by a particular correctional officer or nurse, a chaplain, or even a fellow inmate. However, for inmates not formally assigned to a mental health caseload, case managers can serve as the first line of intervention, referring the inmate onward if more extensive service is warranted. Moreover, for short-stay inmates, tenure in jail may be an important opportunity for case managers to ensure appropriate referral to the social service or mental health service delivery system in the community.

For more extreme psychiatric crises, intervention might consist of longer sessions with higher-level mental health professionals. These sessions should focus on identifying personal strengths, which will help the inmate cope with the experience. Often, providing an understanding that others have gone through similar crises and survived can be reassuring. During periods of extreme psychological stress, a real part of the value of a therapist or counselor is to be a nonthreatening source of company. It is comforting simply to be listened to, especially in the middle of what may be perceived as an abusive experience. Inmates who experienced physical or sexual abuse or torture as children may experience incarceration as a reenactment of this trauma (Dvoskin 1990), and may be especially responsive to such support.

For those inmates suffering from severe mental illnesses, the immediate focus of therapy is to protect the inmate from deteriorating in response to the correctional environment. People with schizophrenia especially seem to have trouble adapting to environmental change and may require a great deal of support. One benefit of psychotherapy is to provide the seriously mentally ill inmate with a touchstone to aid in reality testing, to avoid withdrawal into psychosis in response to both real and imagined fears of staff or other inmates.

Group therapy

Group psychotherapy is the most cost-effective method of mental health treatment in corrections (Metzner et al. 1998). It is an ideal modality for providing much-needed services to large numbers of inmates despite the common paucity of resources. Moreover, group therapy sessions may be conducted independently, or be co-facilitated by mental health staff with varying levels of professional training. Creative and thoughtful matching of mental health staff expertise with the subject matter of the therapy group can be of great benefit. For instance, practical and applied topics, such as anger and stress management, are ideal material for correctional group work. Utilizing a staff psychologist (Masters or Doctoral level) in combination with a social worker or case manager affords participants with complementary balance in perspective and feedback. Alternately, a psychiatric nurse may be the ideal candidate to run a medication education or life skills group.

In the correctional setting, group therapy presents a unique set of challenges for participants and practitioners. Particularly when nondoctoral level practitioners facilitate groups, it may be quite useful to engage in active consultation and supervision processes (Morgan et al. 1999). For the participants, confidentiality is often a primary concern. Inmates must be counseled during pre-participation screening as to the importance of maintaining confidentiality of disclosures in the group setting. Other potential problem areas include security constraints, volatility and possible safety issues, and scheduling difficulties inherent to an institutional setting (Metzner et al. 1998).

Substance abuse

As many as 75% of all prisoners can be characterized as having a history of alcohol abuse or illicit drug use (U.S. Department of Justice 1999; James and Glaze 2006). The high rate of comorbidity between substance abuse or dependence and mental illness (Carey 1989) may be nowhere

more apparent than among the offender population (Abram and Teplin 1991; Edens et al. 1997; Swartz and Lurigio 1999; James and Glaze 2006). Abram (1990) demonstrated the high prevalence of inmates with co-occurring disorders, including substance abuse and depression, most often with antisocial personality disorder being the primary syndrome.

For inmates with co-occurring mental health and substance abuse disorders, accurate diagnosis and subsequent treatment planning are complex, primarily as a result of the complicated symptom picture presented (APA 2015). Symptoms of one syndrome often mask those of another, and abuse of alcohol and other drugs can exacerbate psychiatric symptoms and even bring about psychotic episodes that may persist after intoxication subsides. The unfortunate result is that the presence of co-occurring disorder is often missed during the screening process (Edens et al. 1997).

Indeed, these co-occurring disorders are a growing concern among virtually all segments of the mental health system. The needs of the multiply–disordered population continue to rise and clearly must be addressed (Abram and Teplin 1991). The greater the relevance of substance abuse in an inmate's criminal background, the more important it is to identify and treat the problem, and to continue services upon release (Rice and Harris 1997). However, despite a growing number of treatment options, correctional facilities do not appear to have kept up with the demand for services (Metzner et al. 1998; Swartz and Lurigio 1999; Mears et al., 2002; Chandler et al. 2009). Toward the goal of improving treatment programming, the APA (2015) offers the following strategies to address the issue of co-occurring disorders in the correctional setting:

1. Integration of substance abuse and mental health treatment
2. Treatment of each disorder as primary, while appreciating potential interactions
3. Comprehensive assessment and consultation, focused on individualized planning for treatment of psychosocial issues and skill development
4. Cautious use of psychotropic medication
5. Context-specific interventions
6. Extension of treatment services into the community

STAFF TRAINING AND CONSULTATION

"One of the biggest barriers to care for offenders is the mutual distrust that exists between mental health providers and the community correctional system" (Roskes and Feldman 1999, 1615). Ongoing communication between mental health and correctional staff is an essential feature of effective treatment and intervention programs. Mentally ill offenders present a unique set of concerns in the correctional setting, and management difficulties may arise when correctional officers receive minimal or insufficient training about mental health issues (Versey et al. 1997).

Screening is essential to identify inmates and detainees in need of clinical attention upon arrival, and their subsequent mental health depends in large part on the ability of correctional officers to identify inmates in psychiatric distress and make appropriate referrals. It is therefore important to provide officers with basic training in identifying some of the signs of emotional disturbances, in addition to training the officers how to convey their observations to clinicians. With the well-documented rise in the number of mentally ill inmates nationwide, correctional staff are increasingly likely to be confronted with issues surrounding mental illness in the course of their daily work.

All new employee orientation processes should include a mental health component, presented by a member of the mental health staff. This training is certainly not meant to make diagnosticians of correctional officers, although correctional officers can supplement the efforts of clinicians by learning to assist inmates in coping with the everyday stresses of incarceration (Lombardo 1985). As has been discussed elsewhere in this chapter, staff training can be beneficial for all parties, particularly in facilitating the early recognition of psychiatric decompensation, suicide risk, and crisis intervention. Perhaps the most influential feature of facility-wide staff training, however, is an understanding of how to access available mental health resources when they are needed.

The importance of maintaining an open discourse and rapport between mental health and correctional staff cannot be overstated. The development of a trusting working relationship with officers allows mental health professionals the opportunity to offer opinions and/or suggestions that may diffuse potential psychiatric crises, thereby saving precious time, energy, and resources. Consultation between security and mental health staff will often revolve around the correctional management of inmates or detainees (Brodsky and Epstein 1982). A simple decision to separate two inmates can often prevent a dangerous assault or a psychiatric crisis, and administrators who learn to trust their clinical staff come to value advice in such decisions. Other common topics of consultation include, but are not limited to, assignment to appropriate housing or work detail, and appropriateness for various facility programs or educational opportunities.

Mental health staff have much to offer security personnel in terms of consultation and information sharing, and the benefits of communication are far from unilateral. Ensuring correctional personnel that their opinions and observations are meaningful and important, and welcomed by mental health staff, allows for virtually constant observation of inmate patients. Mental health staff are in direct contact with inmates for only a very brief period of time. Even those inmates participating in frequent therapy sessions still spend the vast majority of their days under the watch of correctional staff. Officers who observe and/or work with inmates on a daily basis often become very familiar with a given inmate's regular presentation. Therefore, officers are likely candidates to note subtle or progressive deterioration in an inmate's functioning. Allowing officers an opportunity to comfortably inform mental health staff

of their concerns about an inmate is an effective method of heading off potential crisis.

Correctional officers can also be extremely helpful in teaching mental health staff about the stresses of day-to-day correctional life in cell blocks and housing units, and how to contribute to a safe institution. When training between correctional and mental health staff members is truly reciprocal, it helps to alleviate some of the natural tensions that occur. On the other hand, if mental health staff present themselves as having all of the answers, it can bolster the long-held myth that security and treatment are competitors. In fact, the opposite is true. Security and treatment are interdependent; without a safe environment, it is very hard to provide meaningful treatment, and without meaningful treatment, the correctional environment becomes more dangerous and unpredictable.

Finally, in addition to treating inmates, mental health professionals can help to reduce job-related stress among correctional line staff (Dembo et al. 1986–1987). Employing an open-door policy for correctional staff, providing literature on stress management, and/or offering consultation and referral services, allows officers an avenue of recourse when work stress becomes overwhelming. But providing mental health services to fellow employees is not recommended, due to the high likelihood of conflicting relationships. Essentially, all persons who live and work in a correctional facility are faced with similar daily stresses in terms of danger, noise, temperature, and the like. Extreme stress in officers may inherently compromise officer–inmate relations, in turn leading to exacerbation of inmates' psychological issues. Once again, open and active discourse, and simple human support may be among the most vital components of a successful program.

SPECIAL HOUSING AND MANAGEMENT OPTIONS

The most common reason for referral of an inmate to mental health services is disruptive or violent behavior, either toward self or others. Frequently, mental health staff will be asked to make a judgment about the level of supervision required to keep the inmate and others safe. Alternatives include transfer to a psychiatric facility, one-to-one or constant observation status, movement to a safer or more isolated cell, or movement to a cell nearer to the observation post maintained by staff.

Other creative approaches include the use of multibed dormitories for suicidal inmates. Company can help alleviate depression, and inmates who are ambivalent about their own suicidality may watch each other far more diligently than staff. Also, it is easier to watch a group of people in one room than in individual rooms.

It is important to be realistic. It is unfair and clinically inappropriate to order a 5-minute watch when the clinician knows there are inadequate staff to perform it. These orders are perceived by staff as an attempt by clinicians to shift responsibility to less well-paid correctional staff. By working together, it is usually possible to work out an arrangement that is both reasonable and clinically appropriate. For example, an order for constant observation could require three staff to observe three inmates in adjoining cells. An order worded "observe every minute," on the other hand, would allow one officer to walk back and forth, and observe all three inmates quite frequently.

For the very small percentage of inmates with severe mental illnesses whose behavior is extremely dangerous, states are increasingly creating secure treatment environments to provide a modified residential level of care. These specialized mental health programs should offer each inmate at least 10–15 hours of out-of-cell structured therapeutic activities per week and another 10 hours of out-of-cell recreational time per week (Metzner and Dvoskin 2006). There are varieties of methods to provide such treatment in a safe manner, which include the use of therapeutic modules, which are stand-alone enclosures somewhat similar to old fashioned telephone booths.

SPECIAL NEEDS INMATES

Minorities

For some ethnic minorities and non-English-speaking inmates, jails can be frightening and oppressive places. For example, Foster (1988) reports that traditional psychiatric approaches may not work well with Native Americans in the federal prison system. Similarly, among inmates with serious mental illnesses, Black and Hispanic inmates are typically less often served by the mental health system (Steadman et al. 1991). This phenomenon may reflect an unwillingness to seek help from predominantly white providers, reflect difficulties in speaking English as a second language, or a cultural practice to avoid seeking mental health assistance, but may also reflect subtle and even unintentional racism among those same providers. Toch et al. (1987) found a number of ethnic differences in prison infractions, and concluded that subcultural and psychological predispositions may converge to produce prison adjustment problems.

Women

Female detainees may have a variety of special problems in adapting to correctional settings (Sobel 1980). These include the possibility of pre-existing pregnancies, which require prenatal medical care, as well as recent mothers whose forced separation from their infant children can contribute to severe postpartum depression or even psychosis (see, e.g., McGaha 1986). Further, many more women than men are custodial parents at the time of their incarceration, often causing severe anxiety over the welfare of their children.

For some women, being locked up in a very small space by intimidating male authority figures can be frighteningly reminiscent of childhood experiences. For female inmates, especially those who have survived traumas, being strip-searched and showering under observation can

seem abusive. Incarcerated females in New York frequently reported long histories of sexual violence at the hands of fathers, husbands, boyfriends, and strangers (Browne 1987). This abuse is often directly linked to the instant offense, as in the case of women who kill abusive spouses to protect themselves or their children.

Older inmates

The number of older inmates has increased rapidly since 1990, with an estimated increase of 550% (Williams et al. 2012). In the correctional context, due to histories of poor health care and multiple traumatic injuries, it has been suggested that age 50 years (rather than 65 as is the general population) can be considered a useful criterion for identifying geriatric inmates (APA 2015). Generally speaking, the offender population is likely to have conducted their lives in a manner less conducive to good physical health, thereby lowering the threshold for common ailments associated with aging. The elderly inmate is subject to the normal stresses of growing old, along with numerous exacerbating factors such as physical vulnerability to other inmates, estrangement or isolation, and a greater likelihood that they will die behind bars (APA 2015). As this subset of incarcerated offender continues to grow, so too will the incidence of age-related psychiatric and medical disorders. Correctional mental health professionals should be aware of, and plan for, the special needs of the incarcerated elderly.

Physical disabilities

Regardless of age, inmates—much like the general population—present with myriad medical and physical disabilities. Mental health service providers must be mindful of the special challenges posed to inmates who are physically disabled, deaf, or blind. This population may be especially vulnerable in a correctional setting. In addition to predatory peers, the occupational and recreational opportunities may be limited, exacerbating the normal stresses of incarceration. Although it has become clear that jails and prisons are covered by the Americans with Disabilities Act (ADA), the exact requirements of the ADA in prisons are still emerging. Many jails and prisons are composed of very old buildings with poor accessibility; however, staff must ensure that inmates have access to needed mental health and medical services, their physical disabilities notwithstanding (*Pennsylvania Dept. of Corrections v. Yeskey* 1989).

CORRECTIONAL HEALTH-CARE STANDARDS

Numerous sets of standards and guidelines for correctional health-care programs have been promulgated by national organizations such as the International Association for Correctional and Forensic Psychology (formerly the American Association of Correctional Psychology; 2010), American Bar Association (1989), American Correctional Association (2003), American Nurses Association (2013), APA (2015), American Public Health Association (Dubler 2003), National Commission on Correctional Health Care (1996, 1997, 1999, 2008), National Institute of Corrections (Anno 2001), and the United Nations (1975). There is a clear trend that the various state Departments of Correction (DOC) are attempting to conform to some national set of standards (Hayes 1989; Metzner et al. 1990; Metzner 1993; Hayes 2012).

The most current and widely referenced standards and/or guidelines for correctional mental health services have been published by the APA (2015) and the NCCHC (2014a,b). The NCCHC evolved from a program within the American Medical Association that published its first health-care standards for prisons and jails in 1979. The NCCHC standards focus predominantly on general health-care issues, although they have increased their focus on mental health issues in recent years (NCCHC 2008, 2014a,b). The guidelines developed by the APA task force, which assume compliance with the NCCHC standards, provide more specificity relevant to mental health services.

The American Correctional Association (ACA), through an annual Standards Supplement (ACA 2000), has significantly improved recommendations relevant to health services in correctional facilities. Although the ACA standards are less than comprehensive, they are to be applauded for current efforts to upgrade them. The ACA is in the process of developing performance-based standards that will, hopefully, expand the current (ACA 1989, 2000) recommendations pertinent to health-care standards.

It is beyond the scope of this chapter to compare the various national standards and guidelines. Such a comparison has been carried out by Metzner (1993) and Cohen (1998). This section will highlight common areas that are found in these national guidelines with brief commentary relevant to particularly difficult issues.

Guidelines provide a structure for correctional mental health systems by requiring the development of written policies and procedures that are to be reviewed/revised at least annually. They should include, but are not limited to, descriptions of the following characteristics of the mental health system (Metzner 1997):

- Mission and goals
- Administrative structure
- Staffing (i.e., personnel and training)
- Reliable and valid methods for identifying and tracking inmates with severe mental illness (best done via a computerized management information system)
- Availability of treatment programs
- Involuntary treatment, including the use of seclusion, restraints, forced medications, and involuntary hospitalization
- Other medico-legal issues such as informed consent, right to refuse medications, and record release authorizations
- Limits of confidentiality during assessment evaluations and/or treatment sessions with relevant exceptions noted

- Mental health record requirements
- Quality improvement plan
- Training of mental health staff regarding security issues
- Training of correctional staff concerning mental health issues
- Research protocols

The APA guidelines recommend that the fundamental policy goal for correctional mental health care is to provide the same level of mental health services to each patient in the criminal justice center that *should* be available in the community.

APA and NCCHC both support a correctional health-care system that integrates the medical, mental health, and dental systems under a central health-care authority (at the DOC central office level for prison systems). However, it is clear that a variety of different administrative models are effective, depending on a variety of factors, including the size and type of correctional population to be served. The importance of establishing medical autonomy relative to clinical decisions (i.e., not compromised by security reasons) and having regular administrative meetings between the health-care authority and the warden, sheriff, or official legally responsible for the correctional facility is emphasized by these standards.

The NCCHC recommends that staffing levels include a sufficient number of health services staff of varying types to assure timely inmate access to evaluation and treatment consistent with contemporary standards of care. The APA recognizes the importance of a multidisciplinary mental health staff. The need for adequate staffing by psychiatrists is also emphasized due to the unique importance of psychotropic medication as a treatment modality. The APA suggests that in jails, for every 75–100 inmates with serious mental illnesses who are receiving psychotropic medications, there be one full-time psychiatrist or equivalent. In prisons, with fewer admissions, the caseload of each full-time psychiatrist equivalent can rise to a maximum of 150 patients on psychotropic medications.

The APA recommends three levels of mental health screening for purposes of identifying newly admitted persons to the correctional facility:

- *Receiving screening*, which is frequently performed by trained custody staff upon booking, is a process designed to ensure that every newly arrived person who may require mental health evaluation is appropriately referred and placed in the proper living environment.
- *Intake mental health screening* is performed by appropriately trained health-care staff as part of the comprehensive medical evaluation provided to every inmate entering a correctional system.
- *Mental health evaluation* is performed by mental health staff in response to a referral from the screening process, other staff, or by self-referral.

The APA guidelines define mental health treatment as the use of a variety of mental health therapies, including biological, psychological, and social. Mental health treatment is described as occurring in a number of different settings, including

- Acute care (e.g., crisis intervention, infirmary care)
- Longer-term care
- Transitional care (e.g., residential treatment within the correctional facility)
- Outpatient treatment
- Inpatient hospital treatment

Program priorities described by the APA include recognizing and providing access to treatment for each inmate with serious mental illness and consulting with other health-care staff and correctional staff. Both the NCCHC and the APA discuss the importance of adequate discharge planning, which has also recently been the focus of class action litigation in correctional systems.

The NCCHC standards require regular review of inmates placed in segregation units for purposes of determining any medical contraindication for such placements and assuring reasonable access to needed health care. The APA guidelines expand these recommendations to include regular rounds by qualified mental health clinicians in all segregation housing units.

Compliance with the guidelines recommended by the APA task force report and the NCCHC standards will help ensure that the correctional mental health system is able to obtain necessary resources in order to provide adequate mental health services to the inmate population.

Segregation

Over the years, there has been a dramatic increase in the use of long-term segregation (Browne et al. 2011). It is suggested to be the result of a philosophical change in the management of problem inmates, with the underlying purpose of removing troublesome inmates in order to improve the level of safety of the general population (Riveland 1999; Collins 2004). Although this may be the best and only choice for certain inmates, such as when the safety of staff is at risk or for the most dangerous members of prison gangs, segregation should be used much less frequently and with greater caution. Metzner and Dvoskin (2006) recommend several elements to consider as emerging standards of care for the responsible use of segregation for the benefit of the inmates, the staff who oversee them, and as required by law: first, medical and mental health care is legally required and must be continued; second, a suicide prevention plan should be in place and inmates should be consistently monitored by mental health staff during rounds to detect dangerous psychological deterioration as early as possible; and third, incentive programs should be included where segregated inmates have the opportunity to improve and/or gain more control over their living conditions based on pro-social behavior that is definable, measurable, and achievable. Perhaps most importantly, segregation must truly be used only as a last resort

when there is no other reasonable way to mitigate a serious threat to life safety, escape, or the safe and orderly operation of the facility

Long-term segregation for inmates with serious mental illness should be especially avoided, except for extraordinary circumstances, due to the potential physiological harm created by the extreme environment of segregation (APA 2012). Segregation can be very stressful from a mental health perspective, as it typically involves as many as 23 hours in a cell per day, little contact with staff, highly unusual and infrequent social interactions, extremes of noise and silence, and an environment of maximum control. Additionally, the use of segregation can further incapacitate inmates, who may already struggle with atrophied life skills due to their mental illness, from being able to healthily and successfully return to the community. For unusual circumstances that require segregation or an extremely high level of security of a mentally ill inmate for the safety of staff or others, Metzner and Dvoskin (2006) recommend adjusting conditions to include "at least 10–15 hours per week of out-of-cell structured therapeutic activities in addition to at least another 10 hours per week of unstructured exercise or recreation time" (p. 764).

The use of segregation in jails and prisons is controversial, and research on the long-term effects of segregation on mental health is sparse, conflicting, and typically not adequately designed to provide control groups for more meaningful analyses (see Suedfeld et al. 1982; Grassian, 1983; Zinger et al. 2001; Haney 2003). Recently, O'Keefe et al. (2013) found that most inmates, with or without mental illness, placed in long-term segregation housing did not experience significant psychological decline during their stay in segregation. However, inmates in segregation generally experienced more psychiatric symptoms than inmates not housed in segregation, which was largely related to their pre-segregation baseline. Of note, mentally ill inmates generally did not clinically improve while in segregation, which was very concerning, because many were experiencing active symptoms. Despite a paucity of empirical evidence, caution, careful planning, and an exhaustion of other resources should be used when deciding to place an inmate into prolonged segregation.

QUALITY IMPROVEMENT

For many reasons, a robust quality improvement system is an essential component of an adequate correctional mental system. Each facility or administrative authority should prepare a regularly updated quality improvement (QI) plan that systematically sets out to review and improve the quality of mental health services (APA 2015). Important elements of a QI system include quality assurance, peer review, and suicide prevention. The QI process should involve health-care staff at all levels as well as key correctional staff. Without active involvement from custody staff, QI efforts to improve relevant processes will be minimally effective at best. QI assessments frequently demonstrate that what is thought to be occurring in a correctional mental health system is very different from what is actually occurring.

SUMMARY

Jails and prisons are saturated with human service need, and the resources will probably never be adequate. Thus, administrators must take into account which services are most costly and sparse and use these resources judiciously.

Although prisons require a broad array of "community" mental health services, in jails and lockups, resources must be focused on short-term crisis services designed to identify, protect, and treat those inmates who are most vulnerable to suicide, injury, or severe psychological distress. The boundaries between the mental health and criminal justice systems are rarely clear (Dvoskin and Patterson 1998). Nevertheless, each setting and discipline must focus on the necessary interface of services that relate to its population and mission. To this end, active interdisciplinary discourse and cooperation are essential to maintaining the integrity and goals of the mental health and criminal justice systems. This chapter outlines the basic legal requirements for correctional mental health, provides an overview of effective treatment delivery, and proposes a structure for meeting those requirements in a cost-effective manner. Above all, resources must be used efficiently, so that each inmate has timely access to the essential services that the law and human decency require.

The architecture of correctional mental health law

FRED COHEN AND JAMES L. KNOLL

CONSTITUTIONAL SOURCE FOR RIGHT TO MENTAL HEALTH CARE

There is no explicit mention of a right to health care in the U.S. Constitution. If there were it is doubtful that persons in penal confinement would be singled out as recipients when no other persons are accorded this valuable benefit. In *Estelle v. Gamble* (1976) the U.S. Supreme Court determined that within the confines of the Eighth Amendment's prohibition against Cruel and Unusual Punishment prisoners did have an implicit right to medical care. The court limited that right to *serious* medical conditions and avoidance of the unnecessary and wanton infliction of pain. There is a certain logic to the coupling of treatment and the avoidance of pain given the location of the right in the Eighth Amendment. The court has since included pretrial detainees within the scope of that right, relying on the Fourteenth Amendment's Due Process Clause. Detainees may not be punished at all, while prisoners may be punished, just not in a cruel and unusual fashion.

No generalized right to treatment for prisoners was provided by the court, only a right to not suffer *deliberate indifference* in the failure or delay in providing needed care or in how such care was offered for *serious* ailments. *Estelle v. Gamble* involved a claim to inadequate medical care for a back injury suffered by a Texas inmate. Oscar Gamble, in a sense, won the doctrinal battle but lost on his personal claim. The care might have been better, opined Justice Marshall, but it did not descend to the depths of deliberate indifference, the enigmatic culpable mental state fashioned by the court. Justice Marshal did not define deliberate indifference; that would await the 1994 decision in *Farmer v. Brennan* (1994). He did indicate that a claim of negligent care (or malpractice) was not the equivalent of the cruelty; the wanton and needless infliction of pain protected against by the Eighth Amendment (*Estelle v. Gamble* 1976).

With *Estelle v. Gamble*, and subsequently *Farmer v. Brennan*, U.S. corrections has witnessed the launching and then the propelling of a judicially discovered and now judicially policed and enforced constitutional (i.e., national) right of prisoners to correctional health care. Deliberate indifference as a culpable mental state is equated with recklessness, and thus is located between negligence (inadvertence) and intent (acting deliberately to achieve a proscribed result). Deliberate indifference as recklessness subscribes to the more difficult to prove version of recklessness in that it requires actual knowledge of a serious risk rather than the less demanding version that asks whether a defendant knew or should have known of the risk.

There are now thousands of judicial decisions involving the claims of pretrial detainees and convicted inmates that their serious mental health needs were in some fashion violated. Indeed, it is the case that "Inmate lawsuits and court rulings have been the impetus for change for inmate health care delivery and continue to be the principal source of corrections health policy" (Kinsella 2004). Persons in penal confinement may seek damages for failed care or join in a federal class action claim alleging systemic failure and the need for a systemic, curative remedy. The latter are the game-changing cases in the sense that broad, future-oriented relief is required, and it is often very expensive. Clinical staff is to be hired, training required, buildings renovated or constructed, segregation housing and practices altered, records refined, medication revised, and more depending, of course, on the individual case (Cohen 2008, 2011).

THE LIMITS OF CRUEL PUNISHMENT AS A SOURCE OF RIGHTS

The Eighth Amendment prohibits cruel and unusual punishment (U.S. Constitution Amendment VIII). It has been persuasively argued that the normative force of the Eighth Amendment derives from the word "cruel" (Dolovich 2009). Punishment of the convicted in the sense of the intentional infliction of pain *is* constitutionally permissible. It is *cruel* punishments that are condemned. The Eighth Amendment

also has force where punishments are grossly disproportional to the offense, totally without penological justification, or involve the needless and wanton infliction of pain (Dolovich 2009).

The denial of medical, dental, and mental health care as cruel punishment must find its constitutional mooring in the needless and wanton infliction of pain and suffering. Consider for a moment the linguistic and operational differences of a hypothetical, constitutional right to health care for prisoners: *All persons in civil or penal confinement shall be guaranteed access to such health care as will preserve life, health, and dignity.* If enacted, there would, of course, be contentious debates regarding a particular diagnosis or whether a particular modality of care was best adapted to preserve life and dignity. Americans turn to the courts for the interpretation and enforcement of such claims relatively more than residents of other nations (U.S. Department of Human and Health Services 2008). The judicial battles to develop and enforce an affirmative source of the claim (or right), however, would likely be far different than the current situation, where correctional health-care law is extruded as a series of positive requirements derived from a negative injunction regarding cruel punishments.

Inmates with mental illness have had some success in the courts leading to prohibitions and limitations on their being confined in penal isolation (or segregation, solitary, restricted housing) (Cohen 2011). The foundation of such decisions is the recognition that inmates with mental illness suffer more acutely than others. Juveniles have gained similar victories with "special vulnerability" also at the basis of such decisions.

European prisons are also experiencing a significant increase in the number of prisoners with mental illness and share the difficulties experienced in American prisons in providing adequate care (World Health Organization [WHO] 2007). With mental health care viewed as a human right and as a protection for the community, the WHO posits the standard of care for prison treatment as the equivalent of that available in the community (WHO 2007).

The WHO narrative on the essentials of prisoner mental health care is not so different than similar narratives from the United States. The glaring difference is that needs are not expressed in terms of the avoidance of pain, and the standard of care bears no resemblance to the strictures of the United States' judicially invented culpable mental state of deliberate indifference. In addition, there is scarcely a mention of the judiciary in the European scheme of things, while for the United States the judiciary is the creator, interpreter, and enforcer of correctional mental health care (Gordon and Lindqvist 2007; Salize et al. 2007). In sum, the right to correctional health care in the United States, obviously including mental health care, was judicially created from a constitutional amendment prohibiting cruel punishment and as a judicial creation; its future contours and enforcement will also likely depend on the judiciary.

SPECIAL POPULATIONS IN PRISONS

Special population groups, with their varying special needs, are those prisoners who exhibit unique physical, mental, social, and programmatic needs that distinguish them from other prisoners, and for whom staff should respond in a therapeutic, rehabilitative, or supportive fashion (Stojkovic 2005). Recall that the constitutional right to correctional health-care treatment extends only to *serious* medical and mental health conditions. Thus, the constellation of special populations far exceeds the boundaries of the medical model of mandated treatment. Further, there is no constitutional right to rehabilitation (not even clearly so for juveniles). To the extent that certain special needs groups require rehabilitative or vocational help, there is simply no constitutional hammer to swing (Cohen 2008). As examples of special populations, female inmates, the elderly, and juveniles will be discussed.

Female inmates

Female inmates have certain relevant needs that stand out, primarily by way of contrast with males. Females, for example, enter prison with symptoms of clinical depression that far exceed the rate of males, they often are the mothers of young children and remain attached to them in ways many male inmates do not, and they also have a very high rate of involvement with drugs (Bloom et al. 2003; Ward 2003).

"Special needs" membership for females requires heightened attention to abuse factors and trauma during the intake screening phase, and also requires programs that are responsive to such needs. There is no constitutional right to such programs by virtue of gender (Cohen 2004). Females and males are governed by the same constitutional principles governing medical care, but those principles are significantly different operationally (*Monmouth Co. Correctional Institution Inmates v. Lanzaro* 1984). For example, the National Council on Crime and Delinquency reported that some 8649 pregnancies existed in the group of female inmates, or about 9% of the population. In addition, female jail detainees won a right to elective abortion in *Monmouth Co. Correctional Institution Inmates v. Lanzaro* (1984).

There were 111,300 females incarcerated in federal and state prisons as of December 2013 (Carson 2014). There has been a dramatic increase in arrests and incarceration of females since the mid-1970s. No single theory seems to explain this increase, especially at a time when overall crime rates are falling.

The high rate of presenting mental illness in female inmates supports an argument that there should be heightened concern about their needs at initial reception and classification. It seems possible, if not likely, that future litigation will import many of these needs where care is mandated, or through an argument that an anticipatory–preventive response is required.

Older inmates

Older (over age 55) prisoners, numbering 124,400 in state and federal prisons, are somewhat similarly situated to female prisoners. Age alone creates no prison-based constitutional entitlements, but age does present a variety of special needs as to housing and medical–mental health care. Attorney Nancy Dubler and Dr. Budd Heyman point out:

> Socioeconomic status and lack of access to preventive and acute medical and dental care may create as much as a 10-year aging differential to the prisoner. Nationally, the number of inmates 55 and older more than doubled from 1981 to 1990. Estimates are that the number of prisoners over age 50 will reach 125,000 by the year 2000 with 40,000 to 50,000 being over age 65. Given the hyperaging phenomenon of the inmate population, many of these prisoners will be aged and infirm with multiple medical problems. These problems, if they mirror the general population, will include kidney failure, diabetes, cancer, heart disease, dementias, and the other degenerative diseases that fill geriatric practices and long-term care facilities.
>
> Were these abstractions not sufficiently troubling, caring for geriatric inmates is likely to be extremely expensive. Estimates for the care of an elderly inmate range from $60,000 – $69,000 per year, in contrast to about $20,000 per year for non-elderly inmates without AIDS. The majority of these monies cover the costs of medical treatments and medications, special equipment for the handicapped, special education, recreation and work programs, prison hospital beds, and special facilities needed to protect the frail and elderly in the violent prison world. (Dubler and Heyman 2006)

Older prisoners as a group possess at least the same legal rights as other prisoners to medical and mental health care and safe housing. As a group, however, they will require much more, and specialized, care than others, and they are ripe for inclusion in the "special needs" category (Curran 2000). As a group, they also represent the type of problems that prison litigation can highlight and resolve on their behalf. At the policy level, there is the nagging question of why some very old, often infirm, inmates are kept in prison.

Juveniles

At the other end of the age spectrum are juveniles, persons under the age of 18, who constitute just 11,300 (Deitch et al. 2009; Sedlak 2010) inmates out of 2,266,800 total prisoners. Imprisoned juveniles, by virtue only of their age-based status, like females and older inmates, may not now actually have a separate category of legal rights, but their claims are quantitatively different and in a few instances—for example, psychological developmental needs, preventive dental care, large muscle exercise, dietary needs—they may be distinct. Knowledge of their special needs, then, sharpens the existing need to screen, diagnose, and then provide the special care and protection dictated by youth. The special developmental circumstances of youth dictate a far more protective and proactive style than is needed for adults.

Health services for juveniles also present a separate category of needs. Dr. Michael D. Cohen points out:

> The particular health needs of young adults are largely related to the physical, emotional, cognitive, and behavioral consequences of puberty. Impulsive behavior results in high incidence of trauma, sexually transmitted diseases, unintended pregnancy, and suicide among adolescents. Asthma is the most common chronic medical condition, but there are a wide variety of childhood chronic illnesses with a prevalence of one per thousand or less, which may be regularly found in youth served by juvenile justice programs. In addition, chronic problems often begin in adolescence, and health staff must be alert to the onset of a significant symptom to facilitate an early diagnosis and initiate treatment. (Cohen et al. 2006)

There will, of course, be special problems related to consent to medical procedures or medication, special claims to large-muscle exercise based on developmental needs, education on nutrition, concern for abnormal growth patterns, and the like. Given the phenomenon of juveniles being waived to adult criminal courts, it seems likely that the question must eventually be addressed regarding whether juveniles in the adult penal system have a particularized and unique legal right to treatment (or anything else) based on their youth. Juveniles confined within the "civil" juvenile justice system do not have a well-founded constitutional claim to treatment (*Miletic v. Natalucci-Persichetti* 1992; *Alexander S. By and Through Bowers v. Boyd* 1995). What is at best a legally anemic claim within the juvenile justice system will not likely gain in strength for juveniles in adult prisons. Advocates certainly may argue that without early intervention and preventive care, juveniles will likely develop mental and physical disorders. The claim has a ring of plausibility and perhaps should be judicially tested by legal advocates. For now, however, juveniles in adult correctional facilities must meet the serious medical need or deliberate indifference requirements for medical and mental health care. Recognizing the characteristics of adolescence noted above should give those claims a certain priority and lead to earlier interventions and a plausible legal claim to a preventive strategy.

A CONSTITUTIONAL SYSTEM OF CORRECTIONAL MENTAL HEALTH CARE

Extracting the affirmative duties required of custodians and the corresponding rights for the confined from a constitutional source that forbids cruel punishment carries with it inherent limitations on the nature and scope of the duties on government and rights of the confined.

Nevertheless, anchored to the threshold requirements of a serious illness, and limited by a highly restrictive standard for measuring compliance—deliberate indifference—the key elements of a system have emerged. It is important to keep in mind that penal custodians and care providers are held only to the deliberate indifference standard that requires *actual knowledge* of risks for constitutional liability to attach. Thus, it has been argued that the court has encouraged the practice of not seeking and pursuing facts related to risks (Thompson 2010).

The *Estelle* constitutional mandate for correctional health care is a blessing and a mild curse. The ruling carves out mental health and medical care but, as noted earlier, omits many other confined populations desperately in need of care and at the mercy of state legislators and correctional administrators. This leads, for example, to compartmentalizing substance abuse treatment from mental health care when it is perfectly obvious they coexist in a large percentage of prisoners and would benefit from coordinated treatment. *Estelle* does not inevitably create a divide between medical and mental health care, and there is a strong case for the institutional melding of such services (Burns 2016).

With "seriousness" as the constitutional threshold for mandated care, those diagnosed with personality or character disorders may be regarded as less deserving of treatment than those with serious mental illness (SMI) (Ader et al. 2012). Given an approach to treatment driven by legal norms that tend to fragment care, even mandated medical and mental health care typically are treated as separate entities. Here, of course, there is a shared mandate to treat the seriously ill, but compartmentalized thinking then separates two treatment constellations where an integrated approach would make much more sense. This division, analogous to silo compartments, becomes a way of thinking even when there is a shared mandate. For the elderly, women, and youthful offenders, the separation evolves from the legal boundaries that exist, and it will likely ultimately require different policy decisions to remedy their neglected needs.

CUSTODY AND RECEPTION

The constitutional obligation to provide correctional health care is welded to the requirement of actual, penal custody. In *DeShaney v. Winnebago County Dept. of Social Services*, the Supreme Court established actual physical custody as the beginning of the duty of care and also its termination (*DeShaney v. Winnebago* 1989). Without custody, whether it be pretrial detainee status in jail or convicted in prison, there is no obligation to provide care or protection. Although there are differences in the populations of those confined in jail versus those in prison, the legal principles for providing constitutionally mandated care are the same. Detainees derive their rights from the Due Process Clause of the Fourteenth Amendment, while the convicted inmates' rights derive from the Eighth Amendment. Further, whereas jail is a more crisis-oriented care facility, prison will have longer, chronic care obligations (Cohen 2008; Cohen 2011).

As for process, the custodial treatment obligation most clearly begins at the point of reception, with the focus on intake screening and evaluation for security, suicide risk information, and health care, including mental health care. With many detainees and prisoners entering the penal confinement system with mental illness, deliberate indifference may apply where a particular mentally ill individual goes undetected and untreated as a result of a failure to screen or evaluate. The risks from not screening are so high, and the potential consequences so significant, that these risks cannot be dodged by omission. In the same sense that actual knowledge may not be subverted by turning one's back to the obvious, to not hearing the scream for help by closing the door, no jail or prison system may constitutionally operate without screening and evaluation.

The following points are a distillation of the leading standards on reception and intake:

1. *Receiving mental health screening*: Done immediately on admission through brief observation and structured interview. At this point in the process, the screening necessarily casts a wide net. Any suicide ideation or history of hospitalization, for example, leads to further assessment.
2. *Intake screening*: Trained staff makes further inquiry into relevant factors, usually as part of the obligatory comprehensive medical evaluation. This is more extensive than the receiving stage but does not approximate the intensity and professionalism required in the next stage.
3. *Evaluation*: A comprehensive examination by a qualified mental health professional, using clinical interviews, histories, psychological testing, and clinical judgment. Usually conducted only if the inmate screens positive, a "positive hit" at stage 1 or 2 or if the inmate clearly presents with a major illness (Psychiatric Services 2002; American Correctional Association Standards 2003 and NCCHC 2003). Typically, correctional institution policy or legally driven mandates require that such evaluations be conducted within a specific time frame, most commonly within a 2-week period.

The importance of adequate screening and initial evaluation cannot be overstated. Inadequate or misleading information accompanies the inmate and increases the likelihood of an early adverse outcome. The risk of mental

and physical deterioration begins at the front door and may remain uninterrupted by adequate care until a tragic outcome occurs (Dlugacz 2015).

ADEQUATE STAFF, BED SPACE, AND ACCESS

This triad of components may be considered the basic foundation of correctional mental health care. However, there is no specific number or an agreed upon formula for determining constitutionally adequate staff or bed space. Indeed, adequacy itself will likely be determined by the timely access to care component: Do inmates requiring mental health care gain ready access to persons properly trained and certified to diagnose and treat, and is there adequate bed (or treatment) space to accommodate the treatment and housing needs of treatment-eligible inmates?

If a lawsuit is to be settled, then the parties will agree, or the court likely will order, fixed numbers of staff and beds, usually with a time frame for compliance. One example of such an approach is *Dunn v. Voinovich*, where the parties agreed to suspend formal discovery until an independent examination of Ohio's prison mental health care could be completed and results provided to the court. The results of the independent evaluation became the basis for a settlement, and the settlement in the form of a Consent Decree included specific requirements as to staff and bed space. The parties used ratio formulas to arrive at the specifics and importantly agreed that the mental health needs of female inmates were significantly greater than those of males and that a significant upward adjustment was required (DeCou 2001). The parties agreed to a certain number of patient beds, treatment space, and mental health staff. The *Dunn* case illustrates how a lawsuit anchored to the generalities of the Eighth Amendment and the evolving standards of *Estelle v. Gamble* and *Farmer v. Brennan* can morph into a specific set of legally enforceable mandates. Staff and bed space aside, it is the dynamic concept of access to such care that ultimately determines the efficacy of proposed remedies. Where staff and beds may be counted and, thus, objectified, access can be evaluated only by studying the pathways an inmate must negotiate to obtain care.

ISOLATION OF INMATES WITH MENTAL ILLNESS

The Bureau of Justice Statistics (BJS) does not have data on the number of prisoners held in solitary confinement. However, it is clear that reliance on such confinement varies from state to state and that a significant number of the two-plus million people in our jails and prisons are held in such confinement. Isolation units exist within various prisons and may be called control units, special management units, high-security units, administrative segregation, or disciplinary segregation. A supermax prison, in turn, qualifies as an isolation entity unto itself (Cohen 2006). There is some variability in the degree of social and psychological isolation. The most extreme form of isolation, at times referred to as "dark cells," consists of inmates held in solitary confinement and subject to social isolation and near total sensory deprivation by lack of access to light, sound, or fresh air.

Such "first-degree isolation" is characterized by near complete sensory and social deprivation, and remains in scattered instances. What might be termed "second-degree isolation," similarly having roots in the early history of American corrections, is far more common. This form of isolation (often called "segregation") has inmates housed typically in single cells with solid doors for 23 hours a day, with limited access to outside light and air, able to hear some movements outside their cell, and even yell or "tap" (in code) as communication. Meals are taken alone in the cell; exercise is indoors and very restricted, as is access to programs, visits, telephone, radio, television, and showers, and reading material is substantially limited. This is characteristic of the isolation or segregation units noted above and the typical supermax units.

"Second-degree" isolation, or solitary confinement, thus conveys a set of circumstances beyond life in a single, quiet cell. It definitionally includes deprivation of social interaction, the rudimentary sights and sounds of life, and basic decision making in life's most mundane choices. As one moves from such isolation to the still deprived world of ordinary prison conditions, an uncertain line is crossed that divides isolation from the mere harsh conditions of penal confinement. The critical factors in this divide would be out-of-cell time, congregate activity, exercise or "yard time," and access to work and available programs. Put another way, the greater the social isolation and sensory deprivation, the more eligible the unit for being labeled as penal isolation (Cohen 2011). Whether approached as a human rights issue or empirically as the cause of needless, often serious harm, extreme social and sensory deprivation is the subject of contentious debate (Goode 2012). The issue becomes more clearly subject to condemnation where the issue of inmates with serious mental illness in isolation is concerned (Haney 2003; Grassian 2006).

There is no judicial decision finding segregation, even long-term segregation, unconstitutional per se. However, there are several decisions that bar, or severely limit, its use with the psychologically vulnerable and those with SMI (*Madrid v. Gomez* 1995; *Jones 'El v. Barge* 2001; *Austin v. Wilkinson* 2002; *Presley v. Epps* 2005). These decisions are not identical in their reasoning; however, they display common themes. Once the decision is reached that longer-term penal isolation is prohibited for inmates who are, or are at risk of becoming, SMI, there is typically a debate over what diagnostic categories warrant exclusion. What used to be considered Axis I disorders under the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*) would be automatically included. Other populations typically considered for exclusion from longer-term penal isolation include

1. Inmates at high risk for suicide
2. Inmates diagnosed with an organic brain syndrome resulting in significant functional impairment
3. Inmates diagnosed with a severe personality disorder associated with frequent episodes of psychosis or depression and resulting in significant functional impairment
4. Inmates diagnosed with any other serious mental illness or disorder that is worsened by confinement at supermax or segregation

In *Jones' El v. Berge*, the Federal District Court Judge opined that the question of adequate treatment for the mentally ill at Wisconsin's supermax need not even be deliberated, because the conditions themselves were unconstitutional, and no amount of treatment would cure the deficit. A University of North Carolina School of Law study concluded that "The Constitutional protections against cruel and unusual punishment, when considered against the volume of expert findings, must be said to prohibit solitary confinement, as does the Due Process clause…. solitary confinement is ineffective at decreasing violence within prisons; it is ineffective at preserving public safety; it is ineffective at managing scarce monetary resources; and it violates the boundaries of human dignity and justice" (University of North Carolina School of Law 2014). American Bar Association standards have described the isolation of inmates with SMI as "simply inhumane" (ABA 2011). Various states (New York, Ohio, Illinois) have adopted exclusionary rules for the vulnerable populations, to include those with SMI, in their policy and procedures. However, in the authors' experience, such rules not uncommonly fall short of effective in real-world practice and conditions.

OTHER RELEVANT ISSUES

There are a host of other issues relevant to the evolving correctional landscape and commonly vetted by the courts.

Records

Is a modern electronic records system constitutionally required? An electronic record system clearly is desirable, but certainly not required. Regarding constitutionality, the determinative question is the impact on continuity of care. Records are often a significant factor in the concept of continuity of care. With inmate–patients constantly on the move and staff regularly in flux, having decent medical records available when required becomes essential. The significance of records relates most importantly to the quality and continuity of care, and legal challenges to records to be successful must link inadequacy to failure in care.

Consent

Prisoners have a liberty interest in the privacy and security of their bodies (*Washington v. Harper* 1990; *Doe v. Delie* 2001). As a general proposition, inmates must consent to the use of psychotropic medication, although in the case of a genuine emergency there may be room for involuntary medication either for treatment or, less likely, for control. In an emergency situation, in jail or prison, where a prisoner represents an acute danger to himself or herself or others, forcible medication on the spot with no prior hearing is permitted.

Consent is an aspect of personal autonomy, and a fundamental principle of medical ethics. Informed consent requires the individual possess (1) voluntariness of choice, (2) understanding and access to the relevant information, and (3) mental competence to make the decision at issue (Appelbaum 2007). The issue of consent most often arises in the setting of an inmate patient's refusal of psychiatric treatment. Many incidents of treatment refusal are not due to a lack of treatment capacity, but rather to a host of other clinical factors, such as poor therapeutic alliance, inadequate time spent with the patient, objection to specific medication side effects, previous bad experiences with treatment, and fear of the stigma of receiving psychiatric treatment (Buckley et al. 2003). It is when the patient's lack of treatment capacity is truly illness or symptom related that the option of involuntary treatment should be considered.

In this last resort option, many facilities will follow the *Washington v. Harper* (USSC 1990), internal administrative panel model of satisfying the patient's due process rights to refuse treatment. However, the clinician should be aware that individual states may require more stringent standards, such as New York State, which requires a full judicial hearing for inmate–patients who require involuntary treatment (*Rivers v. Katz* 1986). The legal criteria for treatment capacity vary by jurisdiction, and there are no widely accepted curricula on how to evaluate treatment capacity (Kim 2010). Current practice is typically guided and delimited by state laws.

The legal development of informed consent has stressed a functionalist model of competence—which holds that the individual's capacity is determined by demonstrable abilities, as opposed to diagnoses or other psychiatric labels. At the same time, researchers have developed a set of interpretations based on these laws over the past three decades. The "Four Abilities" model developed by Appelbaum and Grisso has seen widespread acceptance in practice (Grisso and Appelbaum 1998). This model is based on a review of statutes, case law, and research data, and requires careful assessment of the following abilities: (1) the ability to understand information relevant to the decision; (2) the ability to appreciate the individual's situation and its consequences; (2) the ability to manipulate the relevant information rationally; and (4) the ability to express a stable, voluntary choice (Grisso and Appelbaum 1998).

Disciplinary hearings

Disciplinary hearings (intra-facility hearings to determine the consequences of disciplinary infractions by inmates) are often conducted by a senior correctional officer in the

presence of corrections staff and the inmate. Punishment for disciplinary infractions may involve a "sentence" of anywhere from 2 weeks in a disciplinary segregation unit to reclassification followed by months to years in a supermax unit. Disciplinary hearings have very serious consequences for mentally ill offenders (Knoll 2008). Inmates with mental illness are more likely to be charged with rule violations than inmates without mental illness, and therefore have an increased rate of disciplinary infractions and placement in punitive segregation (Toch and Adams 1986; Lovell et al. 2000; James and Glaze 2006). The mentally ill inmate charged with a disciplinary infraction may or may not be entitled to mental health consultation or expert testimony, owing to the fact that there is considerable variability in how hearings are conducted, as well as the criteria and procedure for placing inmates in administrative segregation.

In a nationwide survey, considerable diversity among states was found regarding the role of mental health staff in disciplinary hearings (Krelstein 2002). Most states had policies on the issue, but there was no clear consensus on whether mental health staff should offer "ultimate opinions" regarding competency or sanity in the disciplinary process. In addition, the role of the clinician in these hearings may raise concerns about the dual agency dilemma (Metzner 2002). According to the National Commission on Correctional Healthcare recommendations: "the services of outside providers or someone on the institutions staff who is not involved in a therapeutic relationship with the inmate should be obtained" for such proceedings (APA 2000). This is analogous to the ethical bind in which the psychiatrist acts as both treating physician *and* forensic evaluator, and is generally to be avoided (AAPL 2005). If at all possible, the clinician should make efforts to adhere to this policy to avoid harming the treatment relationship. Testimony by an uninvolved clinician may be critical, as the severely mentally ill patient is not likely to be able to effectively advocate for himself or herself or explain his or her mental state at the time of the offense with the same impact as a trained clinician.

Given the trend of large numbers of inmates with SMI, as well as the growing recognition that this population should be kept out of punitive segregation, it seems likely that the need for mental health testimony at disciplinary hearings will become an increasingly formalized process. As usual, legal mechanisms will drive most changes. For example, in *Anderson v. Coughlin* (1987), inmates in several New York Department of Corrections' Secure Housing Units (SHU) alleged, *inter alia*, that their due process rights had been violated by the way that disciplinary hearings were conducted. In 2002, a private settlement agreement regarding the disciplinary due process issue was reached, resulting in amendments to the New York Department of Corrections' SHU regulations. The agreement required specific criteria be used by hearings officers in determining when an inmate's mental state or intellectual capacity is at issue during a hearing. Further, testimony is required by correctional mental health staff to address (1) the extent to which the inmate's current mental health status affects his or her fitness to proceed with the hearing, (2) the extent to which the inmate's mental status at the time of the incident did or did not affect his or her responsibility for the offense, and (3) the extent to which the inmate's current mental health status or clinical history make him or her suitable or unsuitable for SHU placement.

A second example comes from the California Department of Corrections and Rehabilitation (CDCR) in the case of *Coleman v. Brown* (2013). In *Brown*, it was found that mentally ill inmates who acted out were treated with punitive measures without regard to their mental status, or whether the conduct was the result of mental illness. As a result, the CDCR agreed to implement policies and procedures concerning mental health input into the inmate disciplinary process. Part of the process involves an assessment by mental health staff to determine: (1) Are there any mental health factors that would cause the inmate to experience difficulty in understanding the disciplinary process and representing his or her interests in the hearing that would indicate the need for the assignment of a staff assistant? (2) Did the inmate's mental disorder appear to contribute to the behavior? (3) If the inmate is found guilty of the offense, are there any mental health factors that the hearing officer should consider in assessing the penalty? In both *Anderson* and *Coleman*, mental health staff who testify at inmate disciplinary hearings must be trained to do so, and their testimony is subject to review and quality assessment by senior mental health administrators. Although there are nuanced differences, mental health testimony at disciplinary hearings may be roughly analogized to a criminal forensic evaluative process into corrections. As mental health considerations increasingly require attention in disciplinary proceedings (and pre-hearing diversion decisions), the issue of enhanced training for hearing officers has already become a requirement in disciplinary hearing settlement agreements.

SUICIDE

Suicide is nearly always singled out from the larger package of issues related to correctional mental health (*Disability Law Center v. Massachusetts Department of Corrections* 2012). In jurisdictions where general mental health training for staff may be virtually nonexistent, there are almost always a couple of hours of training on suicide prevention, including signs, prevention, observation, cut-down tools, and resuscitation techniques.

In some facilities, suicide observation involves a form of punitive practice, such as placing the inmate with little to no clothing in a cold, dark cell for indeterminate periods. The inmate may be placed in a bare cell for observation, and kept there for days without any sort of treatment. This obviously punitive reaction should be condemned regardless of the clinical status of the inmate. Rather, endorsements of suicidal intent should be treated as occasions for clinical assessment and intervention as needed.

As for suicide attempts and self-injurious behavior, every jurisdiction should have policy and procedure that clearly delineate between a suicide attempt and a gesture and

collect and analyze this data. A useful guide to addressing suicide prevention generally can be found in the American Psychiatric Association Handbook (Simon and Hales 2006), while suicide prevention in correctional settings is addressed in Chapter 56. Correctional suicide prevention policy and procedure must be informed by evidence-based research, current methods of clinical suicide risk assessment, and reliable communication between relevant corrections staff (Knoll 2010).

Theories of liability

There are three primary theories of liability available in constitutionally grounded custodial suicide cases:

1. Failure to provide appropriate medical or mental health care for a serious ailment
2. Failure to provide a non-life-threatening (or safe) environment, translated to a "failure to protect"; and,
3. Failure to train

The first two theories are by far the most popular and at their core represent very different conceptions of the cause of a suicide and the duties allegedly breached. In both instances, deliberate indifference must be shown (Cohen 2011). It should be kept in mind that such suits alleging constitutional violations may be brought in addition to state wrongful death or survival actions, the latter being grounded in ordinary tort law and based on negligence.

A serious mental illness calls for responsive treatment, and when such treatment does not occur or is rendered with deliberate indifference, liability may exist. The duty here, of course, is responsive treatment with a goal to at least ameliorate the illness and prevent the suicide. An inmate may not be known to be mentally ill; for example, an arrestee demonstrating odd or unusual behavior with no known history of mental illness. The jailers' duty in such a case is to act preventively and not necessarily provide treatment. This means a "safe cell" and observation with no immediate, concomitant duty to treat (*Taylor v. Wausau* 2006).

Custodial suicide cases brought in federal court are notoriously difficult for plaintiffs to win. The cases falter on the actual knowledge of risk aspect of deliberate indifference. There must be clear, unambiguous evidence of a serious risk, and where this exists, it still may fall short of deliberate indifference. For example, in *Freedman v. City of Allentown* (1988), arrestees with "hesitation marks" on their throat and who were known to have made an attempt at this same jail were found not to present an imminent serious risk. Litigating individual cases for damages has not had the impact on change that class action, structural injunction lawsuits have. The latter decisions invariably require enhanced training on the subject and require staff to screen and take seriously threats of suicide (Settlement Agreement in *Disability Law Center v. Massachusetts Department of Corrections*).

Another example of the difficult challenge faced by plaintiffs in correctional suicide cases is the U.S. Supreme Court case of *Taylor v. Barkes*, a *per curiam* decision by the Court (*Taylor v. Barkes* 2015). In this case, an intake nurse had learned of a recent suicide attempt by Barkes, as well as his history of psychiatric treatment. Her failure to request enhanced observation did not amount to deliberate indifference. The court held that, at least as of 2004, there was no violation of clearly established law applicable to Delaware detention officials who likely failed to employ adequate suicide screening procedures that could have prevented Barkes' custodial suicide. This legal predicate suggests that the government officials sued in this case may successfully plead qualified immunity as a defense to any supervisory failures regarding the private contractor employed to deliver mental health care. While this decision appears to lower the legal bar for suicide preventative measures, good practice would still dictate proper screening and observation–treatment measures in accord with any perceived risk.

PRISON OVERCROWDING AND INMATES WITH MENTAL ILLNESS

In *Brown v. Plata* (2011), the U.S. Supreme Court issued a five to four decision that is the court's most important decision impacting correctional health care at least since *Farmer v. Brennan* in 1994. Justice Kennedy, writing for the slender majority, noted that the plaintiffs, an inmate class, had convincingly shown that the excessive overcrowding in the California prison system was the primary cause of the unconstitutional denial of medical and mental health care. The decision rests importantly on the language of the Prison Litigation Reform Act (PLRA), which requires a finding of "overcrowding as primary cause" and that no other relief short of the population reduction actually ordered will remedy the violation of the federal right to adequate health care.

In addition, there had to be failed previous orders less intrusive than population reduction orders, and in the case of *Brown v. Plata*, there had been many such failed orders. The lawyers for the inmates made an overwhelming showing on each of these requirements. What some have labeled a "prisoner release" order is actually a prisoner population reduction order. That is, the court upheld the lower courts' decision to require a total prison population not to exceed 137.5% of rated capacity within a 5-year period of time. This involved a reduction of some 46,000 prisoners, but California was allowed to transfer some inmates to local jails, provide for enhanced good time credits leading to a somewhat earlier release, or even build new facilities. In sum, the doors to California's prisons were not suddenly opened.

The overcrowding was linked to the cause of inadequate health care. Its relief, then, simply cleared the path to hiring adequate numbers of treatment staff, creating an adequate number of beds that were varied as to the conditions treated, and assuring reasonable access by eligible inmates to staff and bed space. As Justice Kennedy pointed out, constitutional violation in cases of conditions of confinement rarely are susceptible to a simple or straightforward solution. He pointed to budget shortfalls, a lack of political will,

and systemic administrative failures (*Brown v. Plata* 2011). The California prison dilemma can thus be likened to a spider web, such that when one pulls on a single thread, the entire web is redistributed in a new and complex pattern. Indeed, this is the case in many state prison systems.

California's prison reduction, which fell by 15,493 persons from 2010 to 2011, constituted the most significant prisoner reduction in the nation in that period. A "Realignment" plan, effective October 1, 2011, now promises to be the most ambitious correctional reform in the nation, and with a significant impact on health care. Realignment transfers significant numbers of convicted felons from the state prison and parole systems to the state's 58 counties. This includes nearly all drug and property crimes (Petersilia and Cullen 2014–2015). Jails accustomed to providing crisis care now house offenders serving as many as 10 years, which means chronic health care is on the agenda, and despite some state funding, the jails seem remarkably unprepared as to physical plant, staffing, training, and culture.

SUMMARY

A Council on State Governments Report notes, "Today the most widely accepted policy is to provide inmates with a community standard of care. The community standard of care is based on the level of care someone in the community would receive" (Kinsella 2004). This may be aspirational but it most certainly is not accurate. Indeed, in *Estelle v. Gamble* it was plain that injured inmate Gamble would (or should) receive much more in the way of diagnostic testing if his back injury occurred in the community. It may be accurate to state that a medical procedure or intervention will likely be measured by the "standard of practice," but as for level of care, there is great variation across the country, because the Eighth Amendment proscription against cruelty is a limiting verbal device for an expansive right to treatment. Further, federal courts vary greatly on the norms and enforcement measures for required mental health care. One solution may be to establish a Federal Commission to draft a Uniform Code of Correctional Mental Health Care—essentially a legislative approach to standardizing and subsidizing correctional health care through the federal government.

In sum, the right to correctional mental health care in the United States flows from the Eighth Amendment's proscription against cruel and unusual punishment. Both *Estelle v. Gamble* and *Farmer v. Brennan* establish the inmate's right to medical care—albeit for serious conditions and the avoidance of the unnecessary infliction of pain. Yet the subjective test of deliberate indifference specified in *Farmer v. Brennan* sets an exceptionally high bar, essentially undercutting any generalized right to treatment for prisoners.

SUMMARY KEY POINTS

- The right to correctional mental health care in the U.S. derives from the 8th Amendment's proscription against cruel and unusual punishment.
- The constitutional right to correctional healthcare extends only to serious medical and mental health conditions.
- No generalized right to treatment for prisoners was provided by Estelle v. Gamble, only a right to not suffer deliberate indifference in the failure or delay in providing needed.
- *Farmer v. Brennan* set forth a subjective test for the recklessness required for deliberate indifference—the 8th amendment is violated only if the defendant in question knows there is a substantial risk of harm, yet disregards this risk.
- Deliberate indifference represents a more difficult to prove version of recklessness because it requires actual knowledge of a serious risk.
- The subjective recklessness required by deliberate indifference may encourage a practice of not seeking and/or pursuing facts related to risks.
- A widely espoused policy is to provide inmates with a community standard of care; however, this may be more aspirational than actual.

Correctional psychiatry research

BRUCE B. WAY AND PHILIP J. CANDILIS

INTRODUCTION

This chapter will review why correctional psychiatry research is of critical importance to improving treatment efforts in corrections, as well as to carrying out the mission of evidence-based research in forensic psychiatry (American Academy of Psychiatry and the Law 2015); briefly review research in the major areas of treatments/services provided to the mentally ill in prisons and jails; and discuss practical and ethical issues in conducting correctional research.

Research in the following treatment/service areas will be briefly reviewed: (a) Screening/Assessment Services, (b) Clinic Psychological Services, (c) Medications, (d) Inpatient Services, (e) Crisis Services (including observation cells), (f) Disciplinary Cells, (g) Special Mental Health Residential Units, (h) Discharge Planning, and (i) Telemedicine.

SIGNIFICANCE

More than 20 years ago, Condelli et al. (1994) wrote:

> Reviews of the literature indicate that, until recently, little was known about inmates with psychiatric disorder, and that many professionals working outside of the forensic psychiatry field believe they are untreatable. Adequate programs have been called "virtually nonexistent" for most mentally ill inmates. (p. 63)

There has been major growth in the number of prisoners since these words were written. From 1980 to 2009 jail populations have more than tripled and prison populations almost quadrupled (http://felonvoting.procon.org/view.resource.php?resourceID = 004353). Recent statistics show that on December 31, 2009, there were more than 1.6 million inmates in federal and state prison (West et al. 2010), while 2012 data indicate approximately 750,000 inmates in county or city jails (Minton 2013).

In concordance with overall census increases, mental health caseloads have been rising rapidly (Thigpen et al. 2001; James and Glaze 2006; Way et al. 2008). Beck and Maruschak (2001) reported in 2001 that 13% (151,000) of prison inmates received mental health therapy, 10% (115,000) received psychiatric medication, and 2% (19,000) received 24-hour care for their mental illness. It is now commonly reported that the largest concentrations of institutionalized Americans with mental illness are in correctional environments (Torrey 1996).

Further, unlike free citizens, prisoners have a constitutional right to adequate health care, including mental health treatment (*Estelle v. Gamble*, 429 US 97, 103, 1976; *Ruiz v. Estelle*, 503 F Supp 1256, 1323 [SD Tex 1980]; Cohen and Dvoskin 1996) which has led to an explosion in the number of lawsuits concerning correctional mental health services (Metzner 2002). These lawsuits have produced a dramatic increase and modification in the types of mental health services provided to prisoners.

One of the most useful data sources for enumerating and describing prisoners with mental illness have been the periodic surveys conducted by the Bureau of Justice Statistics (BJS) at the U.S. Department of Justice. Every 5 to 6 years they conduct a "Survey of Inmates in State and Federal Correctional Facilities" and a "Survey of Inmates in Local Jails" which includes sections on mental health. These are the only national sources of data on prison and jail inmates with mental health problems. Unfortunately many of these surveys are almost 10 years old and no new surveys of mental health services are planned (email April 2015 from BJS).

As of 2000, a large percentage of prisons provide mental health services. It is expected that these totals are larger in 2016. Beck and Maruschak (2001) report there were about 1600 U.S. prisons. Of these, 78% screened for mental illness at intake, 79% provided psychiatric assessments, 63% provided 24-hour care for the mentally ill, 84% provided therapy, 83% distributed drugs, and 72% assisted the mentally ill on release.

Although correctional mental health treatment has become a legal and clinical imperative, the research base is quite modest compared to psychiatric research in other

settings. For example, hundreds of papers examine emergency room decisions to admit patients to inpatient services (e.g., Way et al. 1998), but there are only a handful of studies on the crisis services in jails and prisons. This lack of site-specific research is due partly to the reluctance of correctional authorities to permit research activities that may lead to litigation (Metzner 2002). Fortunately, this may be changing since litigation often requires correctional systems to maintain databases of outcome measures for mental health services. Wakai et al. (2009) are among those who report that "there now appear to be signs of interest in and support for research with inmates by correctional agencies, academia, and health care organizations" (p. 743).

This imperative leads directly to the importance of addressing the complex ethical concerns that arise within total institutions, as well as from the unique logistical difficulties in conducting potentially coercive research.

MENTAL HEALTH SERVICES IN JAILS AND PRISONS

Screening for mental illness

Most prison and larger jail systems have a separate unit dedicated to identifying the needs of incoming inmates. Prior records are often sought, structured assessments conducted, diagnoses established, and treatment plans initiated. Of course, this is not just for mental health needs, but for all inmate needs, including security classification. The risk inmates pose to themselves and others is a common consideration upon entry into the correctional system and is mandated by the body overseeing correctional health care, NCCHC.

Prevalence of mental disorders in prison and jail populations is one of the few areas that has been well studied. More than a hundred papers report prevalence of mental disorder (e.g., Goff et al. 2007), although it is difficult to reconcile the large variability in these estimates. This variability even exists within BJS studies. For example, James and Glaze (2006), using self-report data, found that 56% (705,600) of prison inmates, 45% of federal prisoners (78,800), and 64% (479,000) of jail inmates had a mental problem. These percentages are considerably larger than a previous BJS report (Beck and Maruschak 2001), also using self-report data that 16% of state prison inmates thought they were mentally ill.

Another focus of research is measuring "serious" mental illness (SMI); this results partly from the litigation in many states to remove SMI inmates from disciplinary units. For example, Steadman et al. (2009) and Ditton (1999) report that about 15% of jail and prison inmates are diagnosed with SMI. This is much higher than the community estimate of 5%. (Kessler et al. 1996). However, differing definitions of "serious" confound easy comparisons between studies.

There also have been dozens of studies that have found that mentally ill prisoners have numerous and more serious comorbidity compared to their non-mentally ill cohorts, from serious physical health conditions and substance abuse to homelessness and prior criminality. For example, James and Glaze (2006) report that mentally ill inmates have higher rates of prior arrest, incarceration, substance abuse, and homelessness in the year before arrest, as well as greater past physical or sexual abuse. Way et al. (2008), in a cohort study of incoming state prison inmates with SMI, found that 28% had four or more prior psychiatric inpatient hospitalizations, that almost all had a prior psychiatric hospitalization at least 20 years ago, that 62% had a prior suicide attempt, and that 59% had received prior inpatient treatment for substance abuse. Ditton (1999) found that mentally ill prison inmates were more likely to be under the influence of alcohol at the time of their arrest, to be incarcerated for a violent offense, to be homeless, and to have been subject to physical and sexual abuse.

Only a handful of studies provide information on the methods and effectiveness of routine jail and prison screening procedures. The evidence that does exist suggests that much improvement is needed. Trestman et al. (2007) found a considerable number of jail inmates with current and historical psychiatric illnesses had not been identified at intake. Treatment could not begin nor could services be arranged for individuals who slipped through institutional screening procedures. The authors state unequivocally that "high levels of psychiatric morbidity with associated functional impairment exist despite increases in institutional awareness of and attempts to identify inmates with past evidence of psychiatric illness… There is little evidence that these jail inmates had recovered from a past illness, and a greater likelihood that they were chronically impaired by undetected psychiatric illness" (p. 490). There is further evidence that screening procedures cannot simply rely on prior treatment records. James and Glaze (2006) report that 40% of jail inmates and 30% of prison inmates reported psychiatric symptoms without a recent history.

During the intake process a psychiatric diagnosis is assigned to initiate the development of a treatment plan. However, there is almost no research on the accuracy or reliability of these diagnoses, or if and how they account for an inmate's criminality. Way et al. (2008) describe the process of developing a psychiatric diagnosis during the intake process in New York state prison and measures consistency over time. A psychologist or social worker develops an initial diagnosis within a few days in prison basing the information on an interview and available records. This initial diagnosis is reviewed by a psychiatrist a few days later. The authors report that the psychiatrist's diagnosis is identical to the initial diagnosis 95% of the time. The authors then compared the psychiatrist's diagnosis created during intake with the diagnosis at 6 months: 80% were still identical. It was expected that there would be more change in diagnosis at 6 months because treatment and additional assessments had occurred. For example, a *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*) diagnosis of Psychotic Disorder NOS (not otherwise specified) could evolve into Schizoaffective Disorder or Schizophrenia, diverging from the initial categorization.

CLINIC AND PSYCHOLOGICAL SERVICES

Prisons and larger jails contain a mental health clinic, which is analogous to an outpatient clinic in the community. Inmate–patients are escorted to these clinics for psychological and psychiatric treatment. James and Glaze (2006) report that 156,000 state prison inmates received professional mental health therapy in 2004, up from about 130,000 in 1997.

There has been very little research on what kinds of therapy are provided and their relative effectiveness. This deficit persists despite numerous studies that suggest inmates have more complex comorbidity than their nonincarcerated cohorts. Further, numerous commentators (e.g., Ax et al. 2007) stress the need for research on a broad range of interventions provided by the correctional psychologist exactly because of inmates' complex and comorbid presentations.

A recent study has begun the process of describing the therapies provided in correctional environments and has developed a model for understanding the various goals of these treatments. Bewley and Morgan (2011) surveyed 230 mental health professionals across 165 state prisons and asked what psychotherapeutic services they provided, the amount of time spent on each, and their opinion on the relative effectiveness of the services. Almost all 230 respondents were psychologists or social workers. They spent 38% of their time on individual counseling, 36% on administrative duties, and 13% on group therapy. In a survey with 16 content areas and 38 therapeutic factors, a factor analysis produced six goals: (a) mental health recovery, (b) emotional management, (c) institutional functioning, (d) reentry (vocational needs), (f) risk need (criminal recidivism issues), and (g) personal growth. The survey respondents thought they were particularly effective with recovery from mental illness and skill development.

MEDICATIONS

In underscoring the increased needs of mentally ill inmates, James and Glaze (2006) report that 15.1% (185,000) of all state inmates received a psychiatric medication in 2004; an increase of 12.3% (130,000) from 1997. No studies on types of medications administered and their relative effectiveness are available, nor whether certain medication classes are even needed for correctional populations. This dearth of data is quite surprising given the high costs of medication and the common efforts to restrict formularies. Without adequate data on usage and effectiveness, policy efforts to reduce medication costs cannot succeed.

INPATIENT SERVICES

Way and colleagues (Way et al. 1990; Way et al. 1991) documented the numbers of forensic inpatient beds and their staffing almost 25 years ago. More recent data on number of inpatient beds for prisoners are not available, but James and Glaze (2006) report that in 2004, 3.1% (38,000) state prison inmates had an "overnight hospital stay" for mental health treatment compared to 3.8% (40,000) in 1997. Only Reed and Lyne (2000) report on the effectiveness of inpatient treatment for mentally ill prisoners. The authors concluded, based on their review of 13 prisons with 348 psychiatric inpatient beds in England, that "the quality of services for mentally ill prisoners fell far below the standards ….Patients' lives were unacceptably restricted and therapy limited" (p. 1031).

EMERGENCY SERVICES CRISIS OBSERVATION CELLS

Most correctional environments contain crisis cells where inmates are sent from the general population for short periods. In many ways these are analogous to emergency room services in general hospitals. They offer short-term stabilization, the initiation or adjustment of psychiatric medications, assessment for transfer to inpatient treatment, and suicide observation and prevention. These cells are frequently open on several sides to permit staff observation, and usually require removal of an inmate's personal property and clothing. Crisis cells are a frequent target of lawsuits (e.g., *DAI v. New York State Office of Mental Health* 2002) because of these conditions.

Research on crisis observation cells indicates that inmate–patient satisfaction with observation cells is low. Way et al. (2013) found that transfer to an observation cell was the least favorable option for dealing with suicidal ideation—better only than talking with a correctional officer. Skogstad et al. (2005) report a similar result for New Zealand prison inmates. However, Way et al. (2005) found that crisis cells are effective in preventing suicide while in the cell, although it is unknown whether crisis cells reduce the potential for suicide once the inmate is returned to the general population.

It is unknown how many U.S. correctional institutions use crisis cells, how long inmate patients stay, what conditions are like, and what, if any, therapeutic efforts are provided. To date, there exists no research on what treatment is provided in crisis cells, or their effectiveness.

SPECIAL LONG-TERM RESIDENTIAL CARE UNITS FOR INMATES WITH SERIOUS MENTAL ILLNESS

Many correctional settings have special long-term residential units for inmates with serious mental illness (SMI). Sometimes called "Intermediate Care," these units provide more care than clinic services, but less than inpatient settings. Inmates suffering from SMI are housed separately from other inmates, with most clinical, rehabilitative, and recreation services provided on the special housing unit itself. Correctional officers on such units are typically specially selected and trained. Advantages of such units include

residents being protected from being exploited, assaulted, or harassed by non-mentally ill inmates. Special housing units for inmates suffering from SMI have seen significant expansion in the last decade, primarily as a response to lawsuits focusing on the removal of such inmates from punitive segregation (Kupers et al. 2009).

Studies from the mid-1990s in New York State (Condelli et al. 1994; Condelli et al. 1997) reported that residents with SMI housed in the special units experienced fewer admissions to crisis cells, fewer administrations of emergency medications, inpatient hospitalizations, suicide attempts, and correctional infractions and restrictions. In 2001, Lovell et al. (2001a) studied a residential program for mentally ill prison inmates in Washington state and found that inmate–patients experienced fewer symptoms, infractions, assaults on staff, and higher rates of participation in school and work. In 2009, Kupers et al. reported on the establishment of a "step-down" residential unit for inmates with SMI created in response to a lawsuit to remove them from administrative segregation. Findings included large reductions in rates of misconduct, violence, and use of force.

Way et al.'s (2008) study of treatment for suicidal ideation compared samples from general population and long-term mental health housing. Results suggest that there is in fact reduced stigma in the special residential unit. The special unit patients were much more willing to have suicide observation in their cell (73% versus 16%) and to have mental health staff visit their cells (76% versus 31%) than patients in the general population. The stigma and vulnerability conferred by staff visits and suicide watch remain an important challenge to forensic practitioners in the general correctional setting.

Long-term SMI housing units often set a goal to move inmate–patients back to general population housing. Only one study was found that assessed inmates after transfer. Lovell et al. (2001b) reported that patients were able to maintain decreased psychiatric symptoms after return to the general population from the SMI unit. More research is necessary, however, to determine whether this policy is preferable to retaining inmate–patients with SMI in special units for their entire prison stay.

DISCIPLINARY HOUSING

Studies have long found a strong relationship between mental illness and breaking institutional rules (Toch and Adams 1986). James and Glaze (2006) in their Bureau of Justice Statistics study, report that 58% of inmates diagnosed with mental illness versus 43% of those with no diagnosis violate prison rules. In jails the percentages are 19% versus 9%. Consequently, inmates diagnosed with mental illness are more likely than non-mentally ill inmates to be placed in disciplinary housing.

Disciplinary cells, or "segregation," separate inmates from others and restrict their privileges. Usually the inmate is restricted to his or her single cell for 23 or 24 hours each day and not permitted to work, attend programs, or interact with other inmates. These units vary widely, however, particularly in their degree of "sensory deprivation" and access to mental health services. Many disciplinary cells are "open-celled," which allows noise from other cells.

Placing persons diagnosed with serious mental illness in punitive segregation has been the subject of both correctional research and human rights advocacy. It has also been a leading cause of litigation (Metzner and Fellner 2010; Kapoor 2014). In a landmark publication in 2012, the American Psychiatric Association (APA) published a position paper stating that long-term isolation is harmful to prisoners with serious mental illness, either by directly causing clinical deterioration, or by depriving them of treatment that would have resulted in improvement (APA 2012).

In fact, research has found that punitive isolation is associated with suicide risk (Way et al. 2005; Patterson and Hughes 2008). Further, Way et al. (2007) found that inmate-patients who died by suicide in punitive isolation died soon after transfer. Time in disciplinary cell before suicide had a median of 63 days.

The question of whether punitive isolation actually causes clinical deterioration is far from settled however. Some prominent commentators (Grassian 1983; Haney 2003) argue that disciplinary housing environments deprive individuals of adequate sensory input and thereby directly cause deterioration of mental functioning. However, other reports indicate that no psychological deterioration occurs during short periods of isolation (Bonta and Gendreau 1995; Zinger and Wichmann 1999; Andersen et al. 2003).

There are numerous potential reasons for these conflicting results, and full reviews are available (Suedfeld et al. 1982; Zinger and Wichmann 1999; Haney 2003). One reason for these conflicting results is that the actual amount of sensory restriction varies among disciplinary cell blocks. Indeed, a number of differing constructs may qualify as "disciplinary housing." Some authors report that sensory input in solitary confinement may not be that much different from regular cells, because inmates in solitary still communicate with medical staff, mental health staff, correctional staff, and other inmates. In addition, inmates in solitary may have access to reading material, mail, and radio and television programs—depending on the facility's policy (Suedfeld et al. 1982).

Another confounding variable in the debate over isolation arises from studies that have documented the extreme disability of inmates prior to being placed there. For example, Cloyes et al. (2006) reported that 45% of residents of Washington State's super-maximum security unit had SMI. Kapoor (2014) reviewed the literature and concluded that "although some scholars debate whether isolation is the cause or effect of the dangerous behavior observed in prisoners housed in isolation, it is clear that, at the very least, isolation adds no benefit to the treatment of mental illness in prison" (p. 2).

DISCHARGE PLANNING

Many correctional systems (72% of state prisons according to Beck and Maruschak [2001]) have specific discharge planning services for mental health where counselors set up mental health, housing, and other services in the community. Some states have special discharge planning mental health treatment programs that include an even more enhanced array of services, such as a visit in prison from the community mental health provider.

Although discharge planning may become a new area of prison ligation (Metzner 2002), and there are numerous guidelines for effective discharge planning (Veysey et al. 1997; Lurigio et al. 2000; Draine et al. 2005; Blandford and Osher 2013), none have been tested empirically.

There have been a few studies of reentry mental health programs that show promising results. Hartwell and Orr (1999) reported on a Massachusetts program for inmates with mental illness which provides extra services 3 months before, and for 3 months after, their release. The authors found much lower recidivism for participants. Kesten et al. (2012) describe the Connecticut Offender Reentry Program (CORP) for mentally ill inmates which, beginning 9–12 months before release, includes "a corrections-based Life Skills Reentry Curriculum, collaborative reentry planning sessions to identify and prioritize life concerns, and implementation of the reentry plan through targeted community services and criminal justice supervision" (p. 22). These authors found that CORP participants were only half as likely to be rearrested as inmate–patients who received standard treatment planning services.

Rather than studies of effectiveness of discharge planning per se, a number of studies have examined the outcomes of mentally ill inmates after release (e.g., Lamb et al. 1999). Although both Feder (1991) and Adams (1983) did not find any difference in recidivism between mentally ill and non-mentally ill groups following adjustment for recidivism risk factors, Cloyes et al. (2010) report that serious mental illness (SMI) represents a major risk for repeated incarceration. They found that inmates with SMI had a much shorter median time before return (385 days versus 743 days) than non-SMI releasees. Castillo and Alard (2011) report that mentally ill offenders released from jail with an alcohol problem recidivate earlier. In a study of work release from state prison, Way et al. (2007) found that mentally ill women were more likely to fail than non-mentally ill women, but the difference among male groups was not significant. Further, prisoners transferred to civil inpatient hospitals upon discharge have much longer lengths of stay in civilian hospitals (Way et al. 2004), although differences in severity of illness were not detected between groups.

TELEMEDICINE

Mental health assessment and treatment via computer have been growing rapidly in correctional environments, although the exact rate of growth is not known. Even though more research has been conducted about telemedicine in community settings (e.g., Charles 2000), some groups have studied its use in prisons. Magaletta et al. (1998) report high patient acceptance of the technology, access to a larger range of psychology services, and greater access to inmate–patients for research purposes. They noted that security was easily maintained with telepsychiatry. Zaylor et al. (2001) reported that Symptom Rating Checklist-90-Revised scores improved among inmates treated via telemedicine, and that psychiatrists corroborated the improvement on the Clinical Global Impression Scale. Finally, Kaplan and Lilly (2012) found no difference between telemedicine and face-to-face treatment in the number of crisis admissions and number of inpatient hospitalizations.

DIFFICULTIES AND CHALLENGES OF CONDUCTING RESEARCH IN PRISON AND JAILS

Conducting research in correctional environments is difficult, especially because obtaining approval from correctional authorities and Institutional Review Boards (IRBs) can be time consuming. IRBs require special protections for prisoners entering research, and prison administrators fear the increased likelihood of litigation (Metzner 2002). Due to a history of abuse of prisoners as research subjects, there are enhanced regulations for conducting research with inmates, and prisoners are considered a vulnerable population. IRBs must have a prisoner-representative on the board during deliberation and pay close attention to the research participant's capacity to consent in the coercive prison environment. Consent forms must promise that participation does not affect personal treatment or legal outcomes in the inmate's case, but prisoners may nonetheless participate in order to gain favor.

Cornerstone events leading to this state of affairs include the landmark legal case of *Kaimowitz v. DMH of Michigan* (1973) in which an inmate consented to psychosurgery but was blocked by the district court because of a prison's inherently coercive environment. Further, the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research in its ground-breaking Belmont Report (1979) assumed that informed consent by prisoners was impossible.

Recruitment of research participants is also difficult because inmates are harder to engage than subjects in the community. Prison is not the place for self-disclosure, and inmates fear that information they provide will be used against them. Skogstad et al. (2005) reported that inmates did not trust that mental health information would be kept confidential. Way et al. (2013) found that 42% of mental health patients residing in general population housing were unwilling to tell their counselor that they were having suicidal thoughts. Inmates are commonly ostracized and ridiculed for showing weakness, so that participation in a research project on mental illness may increase stigma and vulnerability.

Some research groups, however, have found that this may be a function of the setting. Way et al. (2013), for example, found that patients in special mental health residential units welcomed cell-side visits from mental health staff, although inmate–patients in the general population did not. Conversely, although Appelbaum, Hickey, and Packer (2001) advocate the inclusion of correctional officers in mental health treatment teams, current findings suggest inmates frequently mistrust correctional officers. Way's group (2013) found that talking to correctional officers about suicidal thoughts was an inmate's least favored treatment option. It was even the least favored option for inmate–patients in special mental health residential units that used correctional officers specially trained in mental health.

Recruitment is also challenging because incentives for participation are rigorously controlled. Even incentives such as small quantities of money will have a disproportionate effect in correctional settings and are almost invariably prohibited by administrators or IRBs. Even small gifts can be stolen or used for illicit purposes. Clinical research with medications may similarly be curtailed because of concerns for diversion or misuse.

After recruitment, maintaining participants in a research protocol remains a challenge. Inmates in jails have short stays that can end unexpectedly as a result of court proceedings. Although prison inmates have longer sentences, they may be transferred to other prisons or housing units, forcing them to drop out of the research.

Most psychiatric research is conducted in the correctional mental health clinic, but getting inmate–patients to the clinic and keeping them there for lengthy treatments or assessments can be problematic. Movement within prison and jails is restricted and carefully choreographed, so that researchers must rely on correctional officers for escorting subjects and meeting schedules. Punctuality and no-shows are a persistent problem. Moreover, the inmate–patient can usually only remain in the clinic for a few hours at a time before security counts interfere.

Research outcomes may be affected by the conflicting goals of the researchers and the institution. For example, a common outcome measure in correctional treatment is the reduction of disciplinary infractions. Staff and correctional officers may affect the measure because of their support (or lack of support) for the intervention. Staff have considerable discretion in formally reporting a behavioral incident or managing it themselves. More broadly, focusing on infractions may detract from goals that foster independence, such as adjustment in the community after release.

Finally, correctional research is challenged by the lack of validation of many assessment tools in the correctional setting itself. Outcome measures are generally developed with and for patients in the community, and have not been adapted for use in jails and prisons. For example, Way et al. (2004) specifically modified a quality-of-life instrument for use in prison.

ETHICAL ISSUES IN CORRECTIONAL PSYCHIATRY RESEARCH

The many vulnerabilities of prison inmates create special ethical requirements for both researchers and institutions (Christopher et al. 2011). As overcrowding becomes the standard across the country, these vulnerabilities create obligatory areas of focus for correctional researchers. As of 2009, over 2.3 million persons are in U.S. jails or prisons (Bureau of Justice 2010), facing a lack of enthusiasm for the provision of medical services (Wilper et al. 2009) and a persistence in mandatory minimum sentences that extend their incarceration.

For a population that is already overburdened with mental illness, substance abuse, infectious disease, and other medical conditions (Greifinger 2007; Okie 2007), inmates are vulnerable to the vicissitudes of poverty, poor education, lack of opportunity, and prejudice that affect life-long access to health care and healthy living conditions. Although inmates make up only 0.8% of the country's population, the estimated 12-month prevalence of HIV, tuberculosis, and hepatitis C in jails and prisons ranges from 25% to 43% (Hammett et al. 2002, Weinbaum et al. 2005). Among inmates with mental illness, 75% are diagnosed with substance abuse as well (Karburg and Mumola 2006). Mental illness itself significantly surpasses community prevalence across the diagnostic spectrum (Dvoskin and Metzner 2006). These characteristics create a unique imperative to conduct research that improves conditions and health-care outcomes.

Engagement in treatment remains a challenge among those who enter the correctional system. Inmates have notoriously poor adherence to treatment both before and after incarceration (Farabee and Leukefeld 2001; Czuchry et al. 2006), with 82% of one classic cohort of over 6000 inmates at high risk for HIV never having seen a primary care provider (Conklin et al. 1998). The return to the community, or reentry, is itself difficult enough to interfere with the need for health care. The challenge of finding housing, employment, and transportation complicates the often anemic efforts of correctional systems to provide community services (Petersilia 2003), resulting in recidivism and even death (Binswanger et al. 2007; Coviello et al. 2010).

Moreover, prisons have often failed to provide adequate medical and mental health treatment (Human Rights Watch 2003; Belenko and Peugh 2005; CDC 2006, Clemmitt 2007; Wilper et al. 2009). Because inmates cannot seek or obtain their own medical treatment, institutions are legally obligated to meet certain minimal requirements, resulting in inmates being the only class of U.S. citizen that has a constitutionally protected right to health care (Candilis and Huttenbach 2015). This historical context adds to the ethical obligation to research individual and population-specific vulnerabilities.

The vulnerabilities of the correctional setting consequently create a unique obligation for investigators contemplating research on the issues facing prisoners. The Belmont

Report (1979), the cardinal guide to human subjects research in the United States, includes institutionalized subjects among those who must be protected from research participation by virtue of their dependent status and potentially compromised capacity to consent.

The federal regulations that codify many aspects of the Belmont Report do not prohibit correctional research, however, but include prisoners among its vulnerable populations, namely children, pregnant women, fetuses, and neonates (45 CFR 46, 2009). Research with prisoners must be reviewed by an Institutional Review Board unaffiliated with the prison involved, and include a prisoner or prisoner representative. The research cannot be conducted at all unless it is relevant to the medical, institutional, or situational conditions inmates face. Research with this vulnerable population, therefore, requires a number of protections that go beyond the common requirements of oversight and consent. The abuses of prisoners in medical research from Nuremberg to modern times are catalogued elsewhere (Harkness 1996; Hornblum 1997), but support the appropriateness of this protective approach.

This protective stance began to shift in recent years as advocates and public health experts recognized that inmates may benefit from access to investigational treatments that were otherwise unavailable (Gostin et al. 2007; Christopher et al. 2011). Others interpreted access to research as an extension of the constitutional right to health care protected by landmark legal cases such as *Estelle v. Gamble* (1976).

The Institute of Medicine (IOM) consequently took up the issue of access to research in 2004, at the direction of the U.S. Department of Health and Human Services (Gostin et al. 2007). Torn by the conflicting duties to protect voluntariness, consent, confidentiality, and access to health care, a committee of the IOM nonetheless recommended permitting more than minimal risk research that could improve the health of the subject. This standard, among those commonly found in pediatric research protocols, lowered the bar on the risk usually permitted in prisoner research.

At the same time, however, the IOM recognized that coercion and oversight remained active policy concerns. They extended the definition of "prisoner" to include those constrained by other requirements of the judicial system such as probation and parole, and endorsed improving overall research oversight. The IOM was concerned that federal oversight (namely through the Office of Human Research Protections, OHRP) may not extend sufficiently to oversee all prisoner research. The IOM therefore advocated extension of the OHRP oversight model to all funding agencies and private institutions conducting prisoner research, creation of a national registry of prisoner research, and appointment of a specific prison research support advocate or PRSA.

A more nuanced view of research risk assessment was recommended as well. Because current analysis of research risk by IRBs is categorical (viz., minimal risk, minor increase over minimal risk, more than minor increase over minimal risk), assessments do not adequately consider specific risks and benefits, or the specifics of the actual confinement or restriction. Therefore, the IOM proposed a risk–benefit analysis similar to the one found in regulations for children. Benefits to prisoners must be clear and outweigh related risks. Even for Phase III research, where effectiveness has been demonstrated, the ratio of prisoner-to-nonprisoner subjects was not to exceed 50%. This assured that prisoners are not merely a sample of convenience.

Finally, in calling for "collaborative responsibility" as an offshoot of the principle of justice that guided the Belmont Report, the IOM recognized the importance of the stakeholders' perspective. From prisoners and correctional officers to staff and administrators, the IOM recommended input at all stages of research. The hope is that any correctional setting can provide the appropriate context for ethical research. This final recommendation would resonate strongly with those who recognized that inmates' personal views of coercion were frequently based on being included in decision-making and being treated respectfully (Lidz 1997; Cusack et al. 2010; Munetz et al. 2014), rather than the restricted freedom of movement.

SUMMARY

Despite large numbers of inmates with mental illness, and serious mental illness, and substantial comorbidity with other disabilities, there has been and continues to be very little research on the effectiveness or even the monitoring, describing, and enumerating of mental health services for prisoners. It is disheartening that even the BJS, the primary national source of statistics, has no studies underway to update already out-of-date information. Although it is challenging to conduct research, it is imperative if we wish to improve outcomes of inmates with mental illness.

Psychopharmacology in correctional settings

KATHRYN A. BURNS

INTRODUCTION

Correctional facilities are obligated to provide psychotropic medication as part of treatment for inmates with serious mental illness, because such inmates have a constitutional right to treatment and the standard of psychiatric care dictates that psychotropic medications are a necessary component of treatment. This determination flows from the U.S. Supreme Court's logic that failure to treat a serious medical need is a violation of the Eighth Amendment's proscription of cruel and unusual punishment (*Estelle v. Gamble* 1976). A federal court then determined that serious mental illness constitutes a serious medical need (*Bowring v. Godwin* 1977). Subsequent federal court decisions have more specifically addressed the need for the "appropriate use of psychotropic medications" as one component of a minimally adequate correctional mental health treatment program (*Ruiz v. Estelle* 1980). The Ruiz Court acknowledged concern about past "inappropriate" use of psychotropic medications in corrections. The concern was reflected in the court's edict that appropriate use of psychotropic medication entails prescription and monitoring by appropriately trained and licensed staff to treat mental disorders, and not solely as a means of behavioral control.

Against this backdrop of judicial skepticism toward corrections and concern about "dangerous" and mind-altering psychotropic medication, correctional facilities and systems must provide constitutionally adequate mental health care (*Ruiz v. Estelle* 1980). This chapter provides recommendations for consideration of medications for inclusion in a correctional formulary and discusses some aspects of managing the use of psychotropic medication in correctional settings. In spite of the focus on psychotropic medication, this chapter does not imply or otherwise endorse the notion that treatment with psychotropic medication alone is sufficient mental health care. Medication is a significant and necessary component of treatment, but not the sole intervention. Other types of interventions to be included in a treatment program will not be discussed as they are outside the scope of this chapter. The discussion about psychotropic medication that follows also assumes that medication is prescribed as part of a treatment plan and, as such, is clinically indicated, and that there are appropriately trained staff in sufficient numbers to periodically monitor response and potential side effects, and adjust the treatment, including medication, as necessary.

FORMULARY CONSIDERATIONS

General considerations

FACILITY MISSION AND POPULATION-BASED CONSIDERATIONS

When considering medications for inclusion on a correctional formulary, the facility's mission and inmate population characteristics are of paramount importance. For example, there are different considerations for jails, with high population turnover and short stays, versus prisons, where stays are generally longer with fewer inmates entering the system annually. Jails must consider a very broad formulary so that medications that are prescribed to detainees entering the jail from the community are continued without interruption, because many detainees will be returning to their community clinic after a very short jail stay. Alternatively, jails could have a narrow or restrictive formulary as long as they provide immediate access to a psychiatrist or other mental health clinician with prescriptive authority to conduct an assessment and make a therapeutic substitution for the community medication if it is not contained in the jail's formulary. The size of most jails does not justify the expense of manning the booking process with a psychiatrist or other advanced clinician, particularly when detainees are received 24 hours a day. Prisons, on the other hand, generally receive inmates on weekdays during regular business hours and hold inmates for longer periods of time. This provides an opportunity to consider a more narrow psychotropic medication formulary as staffing is available to provide reception assessment, therapeutic substitution of medications when necessary, follow-up in the same correctional system using the same formulary, and

adequate time to observe the effectiveness of the medication substituted and make changes as necessary.

Jails are also more likely to receive detainees directly from the community, and the prevalence of substance intoxication and withdrawal is generally higher than that found in prisons. Consequently, it is imperative that jails have immediate access to medications used to treat withdrawal and provide safe detoxification. Although inmates in prison also have a very high prevalence rate of substance use disorders, the likelihood of life-threatening withdrawal is lower than that which occurs in jails. (Most inmates entering prison have already undergone detoxification in jail, although prison clinicians should be prepared to treat withdrawal symptoms, and benzodiazepine use may be restricted for that purpose. Unrestricted access to benzodiazepines in prison settings can create serious problems that are discussed more fully below.)

The very high prevalence of substance use disorders among correctional populations must be considered when developing a correctional system formulary (Karberg and Mumola 2004). It does not provide an absolute ban on including controlled substances in the formulary, but there are correctional ramifications. There is significant risk that the medication would be diverted to someone other than the intended patient, either as part of the facility's black market in which medication and other items are routinely sold, or traded in exchange for cash, tobacco products, food, sexual favors, protection, or other items or services. Security concerns include having to deal with illicit trading, intoxicated inmates, inmate fights, and victimization, all of which present a risk of harm to other offenders as well as security staff who must respond to these challenges. Even if the patient does not intentionally misuse his or her prescribed medication, he or she is vulnerable to intimidation by others to surrender their prescribed medication under threat of, or actual use of, physical force (Burns 2009). The strength of the addiction is incredibly pervasive and consuming for some addicts. Inmates ferment their own alcoholic beverages and have learned which medications or combinations of medications, controlled and noncontrolled substances, can be used to achieve a high (Bartlett et al. 2014). The knowledge that a weaker inmate is routinely receiving a controlled medication on a daily basis can present an opportunity for a steady supply for an addict who threatens or extorts it out of the more vulnerable inmate. Nearly all psychotropic medications are directly administered by nursing staff in correctional facilities (as opposed to giving inmates a monthly supply to keep in their property and take as directed). This is particularly true of medications that have a potential for abuse, misuse, or lethality in overdose. The storage, inventory, handling, and administration of controlled substances add significant nursing time to an already time-consuming system. Also, nursing preparation time can be prolonged if there is a requirement to administer liquid preparations and/or crush the medication prior to administration. (Although crushing the medication and placing it in liquid before handing it to the intended patient may help reduce the likelihood of diversion, it does not preclude it among these populations.) The cost of additional nursing preparation and administration time must also be multiplied by the requirement for multiple daily dosing unless extended release preparations are used which cannot be crushed. Medical administrators must be judicious when considering whether or not to include medication that is not medically necessary, highly abused, and requires special handling to a generally already overburdened medication administration process (Burns 2010).

Notwithstanding the preceding discussion, correctional facilities housing juveniles have different formulary considerations than adult facilities based on the prevalence of certain disorders, specifically Attention Deficit/Hyperactivity Disorder. Juveniles often enter custody on prescribed stimulant medications for well-documented diagnoses of ADHD. In these instances, juvenile facilities may wish to include stimulants on the formulary for continuity of care as well as clinical efficacy. (This is not to imply that adult offenders do not have the disorder, but the prevalence is lower and most adults do not enter jail or prison on prescribed stimulant medication. If continued use is medically necessary, the stimulant can be assessed by way of a preauthorization process to access a nonformulary medication.)

The number of older offenders in custody is increasing rapidly as a result of sentencing, three strikes legislation, and the aging of the inmate population (American Civil Liberties Union 2012). Facilities housing geriatric offenders will have additional factors to consider in weighing medications for inclusion in the formulary. Older inmates are more likely to have comorbid chronic and progressive medical conditions that impact psychotropic medication choices to manage the population. For example, tricyclic antidepressants are inexpensive and effective for the treatment of depression but may be contraindicated in older patients given their potential cardiotoxicity and anticholinergic side effects creating or exacerbating confusion. In this case, stronger consideration should be given to including selective serotonin reuptake inhibitor antidepressants on the formulary and excluding tricyclic medications. Additionally, given the prevalence of dementia, and particularly Alzheimer disease, correctional facilities housing older inmates may consider inclusion of a cholinesterase inhibitor on the psychotropic medication formulary. Although none have been shown to reverse dementia, there is evidence that they stabilize current functioning and delay further cognitive loss (Gunther 2013). These are important goals in correctional facilities aiming to preserve independent functioning as long as possible to reduce the need for more intensive nursing and supportive services. In general, prisons were not built for, or are ready to accommodate, the special needs of older inmates—most facilities use bunk beds and require fairly long walks to meals and clinic appointments, which present challenges to mobility-impaired older inmates. There are

also security issues related to giving inmates canes, walkers, and other mobility aids.

Specific formulary considerations

ANTIPSYCHOTIC MEDICATIONS

Psychotropic medications classified as antipsychotic medications must be available for use in the treatment of schizophrenia and other psychotic disorders. Both conventional antipsychotic medications (the older or first generation of medications) as well as the newer or next-generation medications should be represented on the formulary for reasons that are at least in part related to side effect profiles. The conventional or first-generation antipsychotic medications are efficacious in treatment of psychosis but carry the potential burden of significant side effects related to normal body movement. Dystonia (severe, involuntary, and painful muscle spasms), profound restlessness (akathisia), medication-induced Parkinsonism (tremors and rigidity), and tardive dyskinesia (involuntary, uncontrolled movement of the muscles, most often involving muscles of the face and mouth, including the tongue) are among the types of movement side effects that are seen with first-generation antipsychotic medications (Bezchlibnyk-Butler et al. 2013). Some of them are preventable or responsive to the simultaneous use of antiparkinsonian medications including benztropine, amantadine, and trihexyphenidyl. However, benztropine and trihexyphenidyl have been misused/abused in correctional settings because they produce a type of "high" when ingested, smoked, or snorted. (Liquid or crushing these medications can reduce the likelihood of misuse and diversion but carries the added burdens discussed in relation to controlled substances: different storage considerations, additional nursing preparation time, and additional administration time.) Additionally, neither akathisia nor tardive dyskinesia is responsive to treatment with these medications. Akathisia resolves with the discontinuation of the offending antipsychotic medication, while tardive dyskinesia may resolve completely or lessen in severity with discontinuation of the medication but may also persist permanently. Monitoring of inmate patients prescribed typical antipsychotic medications must include regular examination at periodic intervals for the development of movement disorders for the duration of treatment with the medication. Most correctional systems utilize the Abnormal Involuntary Movement Scale (AIMS) to regularly examine and document the presence or absence of involuntary movements (Munetz and Benjamin 1988).

The newer or next-generation antipsychotic medications have also been called "atypical" because of their chemical mode of action when compared to the older or "typical" antipsychotic medications. Medications in this group include aripiprazole, asenapine maleate, clozapine, iloperidone, lurasidone, olanzapine, paliperidone, quetiapine, risperidone, and ziprasidone. As a group, they are less likely to impact normal movement or lead to the development of irreversible movement disorders. (The exception being risperidone, which does have some dose-dependent effect on movement.) However, these newer agents have demonstrated an increased risk for the development of adverse metabolic effects in patients taking them, which include hyperglycemia, diabetes, hyperlipidemia, and significant weight gain (Bezchlibnyk-Butler et al. 2013). Prescribers must carefully monitor all patients for whom the medications are prescribed for symptoms of hyperglycemia, and use these medications very cautiously with patients with pre-existing diabetes or significant risk factors for the development of diabetes. Baseline measurements of weight, blood pressure, fasting blood glucose, and lipids are recommended for all patients at the initiation of treatment with atypical antipsychotic medications and at periodic intervals thereafter during treatment, in addition to regular monitoring for symptoms of hyperglycemia (e.g., polydipsia, polyuria, weight gain, weakness) (American Diabetes Association 2004). Although monitoring these parameters is not overly burdensome, it can present challenges in large correctional facilities or systems in which inmate movement is highly controlled and medical and mental health services are not well integrated or co-located, so that monitoring body weights, blood pressures, and blood sugars may be more difficult than in a community clinic.

Previously, correctional systems tended to limit their formularies to first-generation antipsychotic medications due to the considerable medication cost differential in purchasing the older, generic formulations of medication compared to the newer and thus patented, name-brand next-generation medications. However, with time, many of the "newer" medications have become available in generic preparations and cost is less a consideration. Other previous considerations included the availability of the older medications as tablets, oral liquids, and injectable preparations (short-acting and decanoate formulations). Having this degree of options in medication formulation is helpful in addressing medication compliance and useful in emergencies. However, this too is changing and the newer, next-generation antipsychotic medications are becoming increasingly available in multiple preparations as well.

Additional considerations regarding formulary inclusion of various antipsychotic medications include clozapine's demonstrated efficacy for treatment of symptoms that have been refractory to treatment with other medications. Inclusion, or at least ready access, to clozapine is therefore important to ensure continuity of care for persons who have been taking clozapine in the community, as well as for use in patients with treatment-resistant symptoms. Some of the atypical medications also have indications for use in the treatment of affective disorders, including depression and bipolar disorder. The capacity to use one medication to treat several types of disorders or symptoms is a cost-effective consideration for formulary inclusion. Last, unfortunately, quetiapine has been abused in correctional populations, and some systems and facilities have excluded it from their correctional formularies (Tamburello et al. 2012).

ANTIDEPRESSANT MEDICATIONS

Depressive illnesses are prevalent in correctional populations (James and Glaze 2006). A variety of antidepressant medications should be available in the correctional formulary to treat this serious psychiatric illness. Tricyclic antidepressants are inexpensive but potentially cardiotoxic and lethal in overdose, necessitating ongoing nurse administration of the medication for the duration of confinement. Selective serotonin reuptake inhibitors (SSRIs) are equally efficacious and have a better safety profile so they could be prescribed as an inmate self-carry or keep-on-person medication. This can reduce the time spent in medication administration activities for nurses as well as inmates, and may enhance compliance.

Typically, monoamine oxidase inhibitors are not included on correctional formularies due to the dietary restrictions and over-the-counter cold and flu medications' potential to interact and precipitate hypertensive crisis. Other biochemically distinct types of medication such as amoxapine, mirtazapine, venlafaxine, and duloxetine may also be considered for formulary inclusion based on good safety profiles and efficacy in treatment of depression and sustaining remission. Unfortunately, bupropion has been widely misused in correctional populations. It has been crushed and snorted to achieve a type of high and so is no longer on many correctional formularies. Trazodone has a small but serious side effect of priapism among men which sometimes requires rapid surgical intervention and may result in permanent sterility. Because prompt recognition of the seriousness of this side effect and rapidly accessing emergency surgical treatment are often hard to guarantee in correctional facilities (prisons particularly are often located in quite remote areas and distant from medical facilities), and due to the availability of many other, safer antidepressant medication alternatives, trazodone is not recommended for inclusion on correctional formularies.

Some antidepressant medications also have demonstrated efficacy in the treatment of anxiety disorders and posttraumatic stress disorder. Paroxetine, venlafaxine, and nefazodone are particularly helpful in this regard. The versatility of some medications in treatment of various types of disorders is another important consideration for medication inclusion on the correctional formulary. Use of these types of medications for treatment of anxiety provides symptomatic relief without having to resort to the use of benzodiazepines, with all of the inherent problems associated with them in correctional settings.

MOOD-STABILIZING MEDICATIONS

Medications typically described as mood-stabilizing medications must be included on the correctional formulary for treatment of bipolar disorder, schizoaffective disorder, and other disorders with a recurrent or cyclical affective component. They may also be prescribed for inmates exhibiting a high degree of impulsivity and aggression. As a group, these medications typically require the most frequent laboratory testing to monitor serum levels of the medication and surveillance for potential effects on other systems such as hepatic metabolism, thyroid and kidney function, and bone marrow production. Lithium is probably the oldest known and least expensive medication of demonstrated efficacy in the treatment of bipolar disorder. It is not always well tolerated. Several medications originally developed as anticonvulsants have been approved by the FDA for treatment of bipolar disorder, including divalproex, valproic acid, carbamazepine, and lamotrigine. Other anticonvulsants have been widely used "off label" in both the community and in correctional facilities for treatment of bipolar disorder (Bezchlibnyk-Butler et al. 2013). Correctional administrators, and ideally, a Pharmacy and Therapeutics Committee that includes representation of psychiatrists and pharmacists, should address whether or not to permit off-label uses of medications as a matter of institutional policy and practice.

OTHER CLASSES OF PSYCHOTROPIC MEDICATIONS

As previously mentioned, benzodiazepine inclusion on correctional formularies should most likely be limited for detoxification and withdrawal protocols, although time-limited use during a psychiatric emergency or when an inmate is experiencing an acute stressor could also be considered. This is due to the high prevalence of substance abuse in correctional populations, the development of tolerance and physical dependence, and the availability of other efficacious treatments for anxiety disorders and symptoms. Certain of the antidepressant medications, as well as buspirone and hydroxyzine, provide alternative and effective treatment of anxiety without the difficulties inherent in prescribing controlled substances.

Inclusion of which types of the various classes of psychotropic medications discussed in the preceding sections as well as any other psychotropic medication placement on the formulary should be based on an analysis of the correctional facility mission, length of stay, age of inmate population, type(s) of serious mental illnesses present in the population, and prevalence of substance use disorders. Additional considerations include continuity of care and direct and indirect costs, including medication procurement, preparation, and administration procedures. In addition to adoption of a standard psychotropic medication formulary, every facility or system must provide a mechanism that permits review and approval to access medications that are not on the formulary. This process must include that medical consideration be given on a case-by-case basis to assure that inmates are not denied appropriate treatment for their serious mental health needs.

INFORMED CONSENT

Although correctional facilities are inherently coercive environments, the principles of informed consent remain applicable, and the nature and purpose of the proposed psychotropic medication, the risks and benefits of the medication, treatment alternatives, and the risks and benefits of no treatment

must be explained in a way that is understandable by the inmate so that he or she can make an informed choice. The discussion and consent to treatment should be documented in the medical record. Inmates do have a right to refuse treatment, and this should also be explained. Correctional policies regarding informed consent, the right to refuse treatment, and the circumstances under which refusals can be overridden should conform to the rules and procedures of the jurisdiction in which the facility is located (National Commission on Correctional Health Care 2014a,b).

DELIVERY/ADMINISTRATION MODELS

Correctional facilities have developed a number of procedural mechanisms to ensure that medications are administered appropriately to inmates. (Medication administration is the act in which a single dose of an identified medication is given to the inmate to whom it is intended.) Virtually all psychotropic medications are directly administered by nursing staff. This is in contrast to other types of medications that may permit an inmate to retain possession of a limited supply of medication to take as directed on his or her own initiative rather than receiving them from a nurse.

Nursing administration of medication is accomplished in a number of ways, including a central administration point such as the infirmary or clinic at which all inmates must line up at certain specified times to receive their medications. This is commonly known as "pill call" or "med line." In this model, the length of the line and whether inmates wait indoors or outside in inclement weather have grave effects on medication compliance rates. In facilities where security concerns or the physical plant itself do not permit inmate movement to a central location for medication administration, a nurse may carry and then administer medications on the inmate housing units. In this situation, there may be a short pill call line on each housing unit. Alternatively, the nurse may walk from cell to cell administering medication accompanied by correctional staff. Many large facilities utilize a combination of these delivery methods, and some systems permit a limited number of psychotropic medications to be self-administered, such as SSRI antidepressants or some of the mood stabilizers other than lithium.

Given the numbers of inmates prescribed psychotropic medication, medication administration can be a very labor-intensive and time-consuming process. This impacts the number of times per day that medications may be administered (some facilities have only two administration times) and seriously limits the ability to use prn medications except under certain circumstances such as specialized mental health housing units with on-site nursing coverage. Fortunately, most psychotropic medication may be taken only once or twice daily given their metabolism. Nevertheless, medication administration procedures and times impact prescribers' medication selection, format (liquid versus pill form), and dosing frequency (twice a day versus sustained release preparations and once a day dosing), so prescribers must be aware of them.

HEAT-RELATED COMPLICATIONS OF PSYCHOTROPIC MEDICATIONS

Some psychotropic medications, particularly antipsychotic and certain antidepressant medications, are associated with an increased sensitivity to sunlight and risk of heatstroke, hyperthermia, and heat prostration. This is believed due to anticholinergic and antidopaminergic activity of the medications. However, there is also evidence of abnormal thermoregulation in individuals with schizophrenia, placing them at increased risk of heatstroke separate from potential medication effects (Charder and Knoll 2014). The occurrence of heat-related problems for inmates taking psychotropic medications may be exacerbated in correctional facilities where living areas have very limited or no means of cooling air temperature and work details may involve being outdoors and engaging in physical exertion during the heat of the day. Sustained high body temperatures that occur in untreated heatstroke may result in brain or muscle damage, kidney failure, coma, and even death.

Institutional staff at all levels (administration, medical, mental health, and custody staff) must be aware of the increased sensitivity of inmates taking psychotropic medications to heat-related problems and develop policies and procedures that ensure recognition of potential heatstroke and permit actions designed to lower body temperature. Generally, these procedures include providing additional water and break times, monitoring indoor and outdoor temperatures, increasing ventilation and instituting cooling measures (additional access to ice and cool water showers), considering the transfer to a cooler area of the institution, and accessing emergency medical care when necessary.

INVOLUNTARY MEDICATION

Medication may be administered forcibly to a nonconsenting inmate during an emergency so long as it is administered for medically appropriate reasons, ordered by an appropriately licensed prescriber, and used for a limited duration of time. These conditions are often specified by state rules and regulations. An emergency is generally defined as an imminent threat to the life or safety of the inmate or others or significant property destruction (National Commission on Correctional Health Care 2014a,b). Emergency administration of medication may prevent the need for the application of physical restraints or be used to assist the inmate in regaining control of his or her behavior if physical restraint is utilized.

Correctional facilities also have the capacity to administer psychotropic medication to competent, but refusing inmates, provided that certain procedural requirements are followed. The U.S. Supreme Court upheld a policy and procedure of the Washington Department of Corrections that permitted the Department of Corrections to approve involuntary administration of psychotropic medication rather than seek such approval from an outside entity, such as a court. The Supreme Court reasoned that correctional

facilities have an obligation to protect the safety of other inmates in their custody, their own staff, and visitors, and have an interest in maintaining order in the facility. Therefore, under certain circumstances, correctional facilities may override medication refusals in instances where an inmate has a mental disorder and poses a likelihood of serious harm to himself or herself or others or is gravely disabled. Washington's policy provided inmates facing involuntary medication the right to a hearing on the issue; the right to notice of the hearing; the rights to attend the hearing, present evidence, and cross-examine witnesses; representation by a lay advisor; the right to appeal the decision; and the right to periodic review of ongoing administration of involuntary medication. A small committee of medical/mental health professionals with no current treatment relationship conducts the hearing (*Washington v. Harper* 1990). The hearing committee may consider security factors, but the decision is primarily a medical decision regarding the necessity of treatment with medication (Cohen 1998). Individual state laws may impose additional procedural requirements beyond these rights that were accepted as adequate by the *Harper* court.

PRESCRIBING GUIDELINES

Correctional facilities and systems must adopt standard policy statements and practice guidelines that are applied consistently by all practitioners with respect to psychotropic medications. This is imperative from a number of standpoints, including that practice guidelines and medication algorithms are the evolving standard of care in modern psychiatric practice. They are typically evidence based, which provides both a scientific basis and clinical rationale for making treatment decisions (American Psychiatric Association 2006). Correctional practice must stay current with community care. It is also important that prescribers working in a particular facility or system are consistent in their medication interventions. This is helpful to inmate patients as it provides for continuity of care across prescribers within a given facility but also when transferring from one prison to the next. It is also helpful in managing psychiatric workloads and inmate expectations. For example, if two prescribers are working at the same facility and one prescribes clonazepam as a first-line treatment for bipolar disorder, it will not take long for the second prescriber's bipolar patients to ask for clonazepam or be switched to the clonazepam caseload. Eventually, many other inmates will present to the first prescriber with bipolar symptoms that were remarkably latent until a benzodiazepine first-line treatment became available at the facility.

Policy statements should also address expectations regarding the frequency of medication management appointments, laboratory studies, and other monitoring parameter expectations (e.g., AIMS exams, abdominal girth measurements). Direction regarding the authorization process for access to nonformulary medications should also be included in the policy.

SUMMARY

Appropriate use of psychotropic medication is a significant and necessary component of treatment for offenders with serious mental illness confined in correctional facilities. It should be prescribed only as clinically indicated and as part of a treatment plan. Correctional facilities must have trained and appropriately credentialed staff in sufficient numbers to prescribe psychotropic medication and periodically monitor inmate patients for their response to treatment and potential side effects, and adjust the treatment, including medication, as necessary. Given national data about the prevalence of serious mental illness in correctional facilities, it is certain that antipsychotic, antidepressant, and mood-stabilizing medication must be available on every correctional formulary, while other types of medication may be considered based on the facility's mission, inmate population characteristics (age, gender, and the types and prevalence of mental illnesses that occur in the population served), and lengths of stay.

The adoption of recognized practice guidelines and medication algorithms for the treatment of various types of mental illness provides evidence-based, medically accepted treatment rationales and uniformity in the provision of treatment. This is particularly important for correctional systems where care is under constant scrutiny and often called into question by inmates, families, advocacy groups, and the courts. Correctional procedures for medication administration may impact medication choice, dosing frequency, and inmate medication compliance. Other factors that are related to psychotropic medication use in correctional facilities that require some special consideration include informed consent for treatment in an inherently coercive environment, vigilance for the possibility of heat-related disorders given the physical environment and inmate work details, and procedures to override medication refusal when clinically appropriate and necessary.

SUMMARY KEY POINTS

- Psychotropic medication is an essential component of mental health treatment for offenders confined in correctional facilities though it must be prescribed in conjunction with other clinically indicated treatment interventions.
- The use of psychotropic medication in correctional facilities requires appropriately trained staff in sufficient numbers for the prescription of

medication, periodic monitoring for response to treatment and side effects and dose adjustment.
- All correctional formularies must contain antipsychotic, antidepressant and mood stabilizing medications given the prevalence of serious mental illness in correctional populations.
- Inclusion of other types of psychotropic medication on the correctional formulary is based on characteristics of the offender population in the facility such as offender age, gender, other types of mental disorders present and prevalence of substance use disorders in addition to clinical efficacy and cost considerations.
- There are some aspects of psychotropic medication use unique to practice in corrections that include medication delivery/medication administration models, informed consent in an inherently coercive environment and the types of processes utilized to permit involuntary administration of medication.

Suicide in correctional settings: Epidemiology, risk assessment, and prevention

JAMES L. KNOLL AND ANDREW R. KAUFMAN

INTRODUCTION

Suicide prevention in correctional settings requires a well-coordinated effort by mental health staff, corrections officers, and correctional administrators. The correctional environment creates special challenges that must be considered in suicide prevention policy and procedure. The correctional psychiatrist must be familiar with the standard clinical suicide risk assessment process, as well as critical nuances of risk assessment particular to correctional settings. Many evidence-based correctional suicide risk factors are known and must be considered during the screening process, as well as at clinically relevant times. This chapter will cover correctional suicide risk assessment and prevention from a psychiatric perspective, as well as the basic elements of correctional suicide prevention efforts from a systems perspective. Special clinical challenges in suicide prevention will also be discussed.

CORRECTIONAL SUICIDE-OVERVIEW

Correctional settings have a heightened risk of suicide due to many factors, including the fact that they are "repositories for vulnerable groups that are traditionally among the highest risk for suicide, such as young males, persons with mental disorders, socially disenfranchised … [and] people with substance use problems" (World Health Organization 2007). Suicide is the leading cause of death in local jails (Noonan and Ginder 2014). For female prisoners, it was the most common cause of unnatural death from 2001 to 2012. The suicide rate for incarcerated juveniles is approximately two times higher than adult inmates. Prior to the 1980s, correctional suicide prevention efforts across the United States were underdeveloped and of inconsistent quality. Legal action and research resulted in more effective suicide prevention policy and procedure, leading to significant reductions in correctional suicide. Whereas suicide among jail inmates in 1983 occurred at a rate of 129 per 100,000 inmates, by 1993 the rate had been reduced by more than half (54 per 100,000 inmates) (Mumola 2005). In 2002, the jail suicide rate had fallen to a third of the 1983 rate (47 per 100,000). Although not as pronounced, a similar trend was observed in state prisons during the same time period. While suicide rates in state prisons have always been lower than rates in jails, the rate of state prison suicide dropped from 34 per 100,000 in 1980 to 14 per 100,000 inmates in 2002 (Mumola 2005).

Clearly, changes made by correctional facilities over the past 30 years have had a powerful effect. Yet because the risk of suicide in corrections remains elevated compared to the general population, suicide prevention efforts endure as a pressing obligation. Correctional suicide risk factors have been researched extensively, and a list of evidence-based risk factors is given in Table 56.1. Due to the special circumstances of the correctional environment, suicide risk factor analyses much reach beyond mere psychiatric pathology and consider a range of unique variables (Knoll 2010). Further, some risk factors apply more strongly to jail settings, while others apply more to prison settings (Mumola 2005). For example, jail suicides typically occur in the first week of custody. In contrast, most state prison suicides occur during the first year of confinement. One similarity shared by jails and prisons is the method of suicide. In both, hanging (or ligature strangulation) is the most commonly used method (Shaw 2004). Thus, suicide prevention efforts must consider architectural approaches to include eliminating ligature points. Regardless of the setting, deaths by suicide in correctional settings have a powerfully devastating impact emotionally, legally, and financially.

The majority of correctional suicide prevention program guidelines, including those of the NCCHC and World Health Organization (WHO), recommend building policy and procedure around the following core elements:

- Correctional staff suicide prevention *training*
- Intake *screening* procedures
- Observation and monitoring procedures

Table 56.1 Correctional suicide risk factors

Demographic Factors
- Male gender (Noonan and Ginder 2014)
- Age 55 and older (Noonan and Ginder 2014)
- White or Hispanic, African American (Hayes 2010)
- Juvenile/youthful status (Gallagher and Dobrin 2006; Roberts and Bender 2006; Noonan and Ginder 2014)

Historical Factors
- Past suicide attempts (Fruehwald et al. 2004; Suominen et al. 2004; Hayes 2010)
- Violent or serious past attempts (Giner et al. 2014)
- History of psychiatric treatment and/or mental illness (Green et al. 1993; He et al. 2001; Goss et al. 2002; Shaw et al. 2004; Way et al. 2005; Daniel and Fleming 2006; Patterson and Hughes 2008)
- History of substance abuse (Green et al. 1993; Gore 1999; Shaw et al. 2004; Way et al. 2005)
- History of traumatic life events: childhood physical or sexual abuse, abandonment (Blaauw et al. 2002)
- Family history of suicide
- Chronic physical illness
- Conviction for a violent crime against a person (especially homicide, rape, child molestation) (DuRand et al. 1995; Mumola 2005; Duthé et al. 2013)
- First incarceration (Daniel and Fleming 2006)

Clinical Factors
- Mood disorder (He et al. 2001)
- Suicidal ideas
- Hopelessness (Ivanoff and Jang 1991)
- Irritation, rage
- Psychotic disorder (He et al. 2001)
- Impulsive, aggressive traits (Dumais et al. 2005)
- Severe personality disorder (He et al. 2001; Black et al. 2007)
- Unwilling to accept help

Social Factors
- Recent harassment: bullying, humiliation, sexual assault, peer conflict (Blaauw et al. 2001; Way et al. 2005)
- Victim of sexual or physical violence (without also perpetrating it) in last 12 months (Encrenaz et al. 2014)
- Loneliness (Brown and Day 2008)
- Overcrowded conditions (Kovasznay et al. 2004; Opitz-Welke et al. 2013)
- Recent life crisis (e.g., loss, family conflict, bereavement, loss of support, recent bad news, recent punitive sanctions, new charges, unexpected sentence) (Kovasznay et al. 2004; Way et al. 2005; Patterson and Hughes 2008)
- Longer prison length of stay (Frottier et al. 2002)

Environmental Factors
- Jails and holding facilities: first 1–2 weeks of incarceration (Hayes 2010; Noonan and Ginder 2014)
- Secure housing unit/isolation/single celled (Fruehwald et al. 2004; Daniel and Fleming 2006; Duthé et al. 2013; Reeves and Tamburello 2014)
- First 2 months of SHU placement (Way et al. 2007)
- Death row (Lester and Tartaro 2002)
- Ligature points accessible

Acute Items
- Suicidal intent
- Suicidal plan
- Available means (e.g., lethal medications, ligatures, sharps)
- Acts of anticipation (e.g., suicide note, putting affairs in order, giving away belongings)
- Anxiety, agitation (Kovasznay et al. 2004)
- Recent substance use or intoxication (Hayes 2010)
- Dysphoric or agitated depression
- Psychosis with delusions of nihilism or doom
- Global insomnia

Other Considerations/Individual-Specific Risk Factors
- Consider vulnerabilities of the individual, and how they may be affected by demands of the correctional setting

(*Continued*)

Table 56.1 (*Continued*) Correctional suicide risk factors

Risk-Reducing Factors

- Receiving visits from family members (Duthé et al. 2014)
- Purposeful activity (Leese et al. 2006)
- Future-oriented thinking, behavior, plans
- Ability to cite reasons for living (Malone et al. 2000)
- Good social support (Eagles et al. 2003)
- Absence of suicidal ideas or intent
- Hopefulness
- Willingness to accept help and/or treatment
- Good therapeutic alliance with treatment provider
- Stable mood symptoms, low symptom severity
- Religious or moral prohibition (Eagles et al. 2003)
- Compliance with effective treatment (Baldessarini et al. 2006)

- Clinical risk *assessment* and psychiatric evaluation
- Risk management and *treatment*
- Effective correctional staff *communication*

These important program elements must be prioritized and vigorously supported by administrative and system-wide efforts.

SCREENING FOR SUICIDE RISK

Screening is the principle way to identify individuals with a potentially elevated suicide risk. There are several key times when inmates should be screened due to an association with increased risk. In jails and other facilities with unsentenced, pretrial detainees, 33% of suicides occur during the first 48 hours and an additional 27% between day 2 and 14 of confinement (Hayes 2010). Thus, it is critical to begin screening right away as part of the admission/booking process. Additional observation during the first 2 weeks in a reception housing area will help identify warning signs. Another critical period for pretrial detainees is upon returning from court after a verdict, sentencing hearing, or other critical adjudicatory outcome.

For inmates in any correctional setting, screening is important at times that have been associated with increased suicide risk, such as after receiving bad news, or after suffering a humiliation. Inmates in punitive segregation and isolation, such as a Secure Housing Unit (Way et al. 2007), are also at an elevated risk and should be screened more frequently and observed daily for warning signs. Punitive isolation consisting of single-cell status has been associated with a particularly high risk for suicide (Reeves and Tamburello 2014).

Another special population with a very high rate, five times the general public rate (Lester and Tartaro 2002), of suicide are death row inmates. Treating psychiatrists on death row may encounter inmates suffering from overwhelming fear, helplessness, recurrent depression, and self-mutilation (Blank 2006). Inmates who are highly antisocial can also be at risk for suicide, particularly when there is comorbid depression and anxiety (Pennington et al. 2014). Familiarity with the evolving research on correctional suicide is a must for proper risk assessment and formulating correctional suicide prevention policy and procedure.

As the evidence base for screening progresses, it is likely that homegrown screening instruments will be replaced by more reliable tools. For example, in a study of 1120 federal inmates, the Suicide Ideation Scale and the Suicide Potential Index on the Personality Assessment Inventory showed good validity (Patry and Magaletta 2015). In addition, Suicide Concerns for Offenders in Prison Environment (SCOPE) and the Suicide Potential Scale have shown promise when tested among adult offenders (Perry et al. 2010). The personality assessment inventory (PAI) has also been shown to have good clinical utility in correctional settings (Wang et al. 1997; Rogers et al. 1998).

Screening should be performed by trained staff. Checklists or validated questionnaires should be utilized to ensure consistent and thorough procedure to identify at-risk individuals. Upon completion of the screening process, there should be clear guidelines as to when and how an individual will be referred for further assessment, and whether the individual should be placed on suicide precautions in the interim. The WHO (2007) recommended a variety of factors to be assessed at screening. These include the following:

- Presence of thoughts of death or suicide, current and past
- Past suicidal behavior, including in the current facility
- Past placement on suicide precautions in a correctional setting
- Prior mental health treatment, including hospitalizations
- Concerns by the arresting officer about suicide in this person
- Family history of suicide
- Recent significant loss (job, relationship, death of family/friend, etc.)
- Recent substance use and/or intoxication
- Appearance or expressions of hopelessness or fear of the future

- No social support
- Very serious and/or violent criminal charge (e.g., homicide, rape)
- A position of respect or prestige in the community
- Bizarre or confused actions, such as in a psychotic or delirious state

SUICIDE RISK ASSESSMENT PROCEDURE

For mental health professionals, it is considered the standard of care to perform an adequate suicide risk assessment (Simon 2002). All inmates/detainees who have screened positive for some level of suicide risk should be urgently referred to a mental health professional. Failing to adequately assess an inmate patient's suicide risk when clinically necessary deprives the clinician of the ability to identify, treat, and manage a patient's suicide risk. A comprehensive psychiatric evaluation is the essential, core element of the suicide assessment process (APA 2003). A thorough evaluation enables the clinician to (1) identify risk factors, (2) assess the overall degree of suicidality, and (3) implement precautions and treatment interventions designed to reduce a specific inmate patient's suicide risk. The value of identifying risk factors goes beyond assessment of risk, in that it allows the clinician to target potentially modifiable risk factors with appropriate treatment interventions. The suicide risk assessment procedure can be taught to mental health staff in the form of a structured, evidence-based training program, resulting in improved patient care and documentation (McNiel et al. 2008).

The clinical assessment for correctional suicide risk should not rely only on a standardized screening instrument or questionnaire but should include a thorough clinical interview that "allows the inmate to express his own subjective experience" (Felthous and Holzer 2006). Suicide risk assessment is a continuous, dynamic process in which all mental health staff should be well trained and ready to perform at any clinical encounter (Daniel 2006). Circumstances in which a suicide risk assessment is clinically indicated include abrupt changes in clinical presentation, and a lack of improvement or gradual worsening despite treatment. In the absence of suicidal intent, it is still critical to assess the degree and intensity of a patient's suicidal ideation. Repeat suicide assessments over time will be required because of the waxing and waning nature of suicidality. Thus, the suicide risk assessment is similar to checking an inmate patient's temperature when clinically indicated to see if he or she has a fever.

An adequate suicide risk assessment does not rely solely on an inmate patient's denial of suicidal intent, but involves an assessment of both risk-enhancing *and* protective factors in the context of the individual's circumstances and clinical status. In one survey of prison inmates, more than 40% reported they were unwilling to tell staff if they had suicidal thoughts (Way et al. 2013). The overall assessment of risk is a clinical judgment call that is clinically informed and supported by information gathered (Simon 2002). The systematic suicide risk assessment procedure includes the following elements:

1. Perform a general clinical evaluation (mental status exam, differential diagnosis, etc.)
2. Review relevant records
3. Gather necessary collateral information
4. Carefully explore suicidal ideation, behavior, planning, desire, and intent
5. Identify risk-enhancing factors (acute, chronic, dynamic, and static)
6. Identify protective factors
7. Synthesize all of the above
8. Employ clinical judgment to assess overall risk level
9. Generate risk reduction plan targeting modifiable factors

It is possible to conceptualize risk factors as falling into two broad categories—dynamic or static (Meloy 2000). Dynamic risk factors are fluid and potentially modifiable. The clinical importance of dynamic risk factors lies in the clinician's potential ability to target him or her with interventions. Static risk factors do not change (e.g., gender, past suicide attempts) and have shown a statistical relationship with suicide risk. Risk assessment should include some form of analysis of risk factors, and a general estimate of overall risk level (low, moderate, or high). The risk level should be followed by a treatment plan that directly addresses each relevant dynamic risk factor, and the clinician's reasoning for choosing or rejecting options.

CORRECTIONAL SUICIDE RISK FACTORS

In the field of suicidology, there has been a shift toward identifying more precise, evidence-based, disease-specific risk factors (e.g., for bipolar disorder [Marangell et al. 2006]), as well as more proximate suicide warning signs such as hopelessness, rage, reckless behavior, feeling trapped, increased substance use, social withdrawal, anxiety/agitation, dramatic mood change, and a lack of sense of purpose in life (Rudd et al. 2006; Jobes et al. 2008). The same shift has occurred in correctional psychiatry, where many of the standard suicide risk factors seen in free society still apply, but where there are also important risk factors unique to corrections.

Correctional suicide research over the past several decades has identified important corrections-specific risk factors. In a review of completed suicides in the California Department of Corrections and Rehabilitation from 1999 to 2004, 154 suicides were examined (Patterson and Hughes 2008). The findings associated with completed suicide included having a history of psychiatric treatment (73%); being single celled (73%); and recent punitive sanctions (e.g., new charges, receiving an unexpected sentence). In addition to the importance of identifying risk factors, clinical experience suggests that it is equally important to consider individual-specific vulnerabilities and their

interplay with the correctional environment (Ivanoff and Hayes 2002). This involves considering how a particular inmate's vulnerabilities are likely to interact with correctional environment demands, such as negative life events or noxious conditions. According to this stress–vulnerability–coping model, it is when the individual inmate's coping resources become overwhelmed that the risk of suicide is enhanced.

Simply asking the inmate about suicidal ideation does not ensure that accurate or complete information will be received (American Psychiatric Association 2003). Suicides may occur impulsively, so that a present state denial of suicidal ideas does not eliminate risk for suicide. Further, individuals seriously contemplating suicide may not report their thoughts (Resnick 2002). In a study of 112 veterans who completed suicide, 72% denied suicidal thoughts to their health-care provider during the last clinical contact before suicide (Denneson et al. 2010). A study of prison inmates found that a third or more of inmates would not report suicidal thoughts to mental health staff for various reasons, including aversion to being placed in an observation cell (Way et al. 2013). Thus, the absence of self-reported suicidal ideas in an inmate patient whose overall suicide risk is elevated must be considered in the totality of his or her clinical circumstances. Inquiring about suicidal ideas is an important part of an adequate risk assessment, but it is only one piece of the overall suicide risk assessment process (Jobes et al. 2008).

The process of eliciting risk factors and assessing suicide risk during the evaluation is both delicate and complex. In the correctional setting, the endeavor may be uniquely challenging due to a variety of correctional culture forces. It is important to be skillful, yet empathic during an evaluation of an inmate patient's suicide risk. The reliability of the suicide risk assessment will only be as good as the interviewer's skill and ability to actively listen and ask the right questions. Thus, it is helpful to be familiar with reliable interview techniques and lines of inquiry (Shea 2002; APA 2003; Shea 2004). It is important that the evaluation of the inmate be performed in a safe and confidential setting. The clinician should not allow convenience or other factors to result in a "cell-side" evaluation, or similar setting that would reduce the inmate patient's willingness to speak about sensitive issues.

MANAGING SUICIDE RISK IN CORRECTIONS

Correctional facilities have a custodial responsibility to provide for the safety of those being kept in custody. Custodial suicide cases turn on three primary theories of liability: (1) failure to provide care, (2) failure to protect, and (3) failure to train correctional staff in suicide prevention (Cohen et al. 2011). From a clinical standpoint, the management of an inmate patient's suicide risk typically involves three main approaches: (1) monitoring/safety, (2) ongoing risk assessment, and (3) interventions to reduce risk. Once screened individuals have been identified as having an elevated risk of suicide, the next steps involve providing safety, providing treatment, and managing the risk. Inmate patients who are at high or unknown risk are observed carefully in a safe environment until their risk diminishes. Simultaneously, a treatment and risk management plan should be crafted that addresses each modifiable suicide risk factor.

Many current methods used for the acutely suicidal inmate have a strong historical influence reflecting correctional policy and procedure. For example, the suicidal inmate may incur loss of privileges, removal of all clothing/bedding, and placement in a bare cell. Other forms of acute prevention include various types of monitoring. There is no substantive research on the effectiveness of these methods, and little is known about what is most helpful to the acutely suicidal inmate.

THE SUICIDE OBSERVATION CELL

The use of isolation for inmates at risk for suicide remains a prominent tool in correctional settings. Assignment to a suicide observation cell generally results in confinement for 23 hours a day. Often, access to family visits, phone calls, and even attorney visits are limited or prohibited. The inmate patient's clothing is usually removed and replaced with a smock made of material that cannot be easily torn or otherwise used to form a ligature. Bedding material is also removed and replaced with a Spartan mattress made of similar "strong cloth" material. Potentially dangerous items, such as razors or plastic bags, are removed from the inmate's possession. Beyond these measure, the presence of less dangerous items, such as reading materials, personal hygiene items (e.g., toothbrush), and writing instruments may vary according to facility practice and the inmate patient's clinical condition.

Some of these procedures may increase safety, but with a potential loss of therapeutic intervention. Further, experience suggests that inmate patients may simply begin denying suicidal thinking in order to leave the often harsh conditions of observation cells. Eighty percent of inmates characterized the observation cell as undesirable (Way et al. 2013). In fact, in order to avoid being placed in such a cell, Skogstad et al. (2005) and Way et al. (2013) have shown that inmates will purposely not report suicidal ideation to clinicians.

INTERVAL MONITORING

Interval observation by correctional or medical staff is a commonly used monitoring procedure. Interval times vary according to facility policy but generally include visual observation every 15, 30, or 60 minutes. Fifteen-minute checks are often used for inmate patients who are either high or moderate risk. Fifteen-minute checks became a standard interval, not as a result of scientific evidence, but out of convenience and tradition. One staff member can

briefly observe a large number of individuals in a very short time while walking down tier hallways.

One potential problem with 15-minute checks is that they still leave enough unmonitored time for an inmate to die by suicide. Hanging/strangulation is by far the most common method of suicide in corrections. Permanent brain damage can occur within 4–5 minutes, and death may occur in 5–6 minutes (American Heart Association 1992). Thus, for some inmates at risk of suicide, the 15-minute interval is too long to prevent serious morbidity or mortality. More than one-fifth of jail suicide victims were found less than 15 minutes after last being observed, and over 6% of all jail suicides from 2005–2006 occurred while the individual was being observed every 15 minutes or more frequently (Hayes 2010). To prevent deaths by suicide in inmates on 15-minute checks, it has been recommend that checks be conducted at irregular and/or staggered intervals (WHO 2007; National Commission on Correctional Health Care 2013).

CONTINUOUS MONITORING

Continuous observation, or 1-to-1 monitoring, is reserved for the individuals who represent an acute or high risk of suicide. Inmate patients on 1-to-1 in correctional facilities are almost always isolated in special cells, where a staff member can sit in front of their cell to provide constant supervision. This is the most costly way to provide monitoring, requiring a staff member's undivided, full-time attention. Constant monitoring is very expensive, consumes disproportionate staff resources, and is unpopular among inmates due to lack of privacy and other concerns. It is used only when the risk is high and for as little time as necessary. The use of video surveillance may not be reliable, and in the case of an inmate with high or unknown risk, this method should not be reflexively accepted "simply because that is the option jail officials choose to offer" (Hayes 2010, 2013). Another strategy involves altering architectural structure so that a greater number of cells are in the line of sight of a staff member. Unfortunately, even with continuous monitoring, suicides still occur due to lapses of attention. Hayes (2010) reported that nearly 1% of jail suicide victims were on constant observation at the time of their death.

THE SUICIDE RISK REDUCTION PLAN

A risk management plan should be crafted immediately after the clinical risk assessment has been completed. Risk assessments should be done at clinically relevant or critical times, such as when the inmate patient experiences a significant clinical change, a change in precaution levels, a stressor, or upon admission and discharge to an inpatient unit. At such times, it may be necessary to obtain collateral data from mental health records, previous clinicians, or relevant social contacts.

The basic principle behind the risk reduction plan is to identify all those risk factors that are potentially modifiable or amenable to treatment, and target them with reasonable treatment interventions. Table 56.2 gives a sample suicide risk reduction plan for a 28-year-old man with depression, heroin abuse, personality disorder, and relationship problems. He was referred for outpatient treatment in the prison general population upon discharge from the prison inpatient psychiatric unit where he had been admitted after attempting to hang himself in his cell. Note how each dynamic risk factor is targeted with interventions that are reasonable and appropriate to the patient's clinical situation. It would be important for the clinical note to contain some clarification of the patient's comprehension and willingness to follow the treatment plan. Interventions may include utilizing evidence-based coping action plans, intensive outpatient treatment, crisis response planning, and other relevant psychosocial interventions (Jobes et al. 2008).

There is general consensus in the professional literature that the "suicide prevention contract" should not replace a comprehensive or systematic suicide risk assessment (Simon 2004; Lewis 2007). At the present time, there are many clear warnings in the literature about the misuse and unreliability of the suicide prevention contract (SPC) (Garvey et al. 2009). There may be many different designations for the SPC, such as, "No Harm" contract, "No Suicide" contract, "Contract for Safety," and others. They all have the putative goal of persuading the inmate patient to make a pact with the clinician not to harm himself or herself. The SPC remains a "questionable clinical practice intervention" (Edwards and Sachmann 2010).

The SPC and its substantial limitations have been well addressed for over a decade (Simon 1999). The main problems with the SPC include the fact that (1) the "contracts" do not protect against legal liability, (2) they are not considered contracts as understood by law, (3) there is no clinical research to support their use, and (4) there is an abundance of literature warning clinicians about their pitfalls. Some clinicians may use the SPC as a cursory or hurried way of documenting a patient's suicide risk. Some may use it as a way of "managing" the patient's suicide risk, failing to understand that it might help assess risk but cannot be

Table 56.2 Sample: Suicide risk reduction plan

Dynamic Risk Factors (Subject to Change)	Management Plans (Discussed with Patient)
1. Depression—moderate	1. Weekly psychiatric follow-up, selective serotonin reuptake inhibitor antidepressant
2. Impulsivity	2. Depakote, DBT program
3. Heroin abuse	3. Abstinence, Narcotics Anonymous (NA) groups, random toxicology screens
4. Life crisis—marital problems	4. Increased frequency of individual psychotherapy

relied on as an evidenced-based practice for preventing suicide. If an inmate patient refuses to contract for safety, this may provide some worthwhile clinical data. But more commonly, inmate patients will simply acquiesce to the contract, which results in a highly questionable intervention.

CORRECTIONAL SUICIDE RISK MANAGEMENT DOCUMENTATION

The primary purpose of documentation is clinical. Documentation is used to serve as a reminder of what has occurred so far in treatment, what has been helpful, and what interventions have not produced meaningful results. This data must be available not only for the primary clinician, but also for other treatment team members, consultants, and future caregivers. The issue of continuity of care is critical and commonly arises in malpractice suits where there occurred some form of communication breakdown between providers. Proper documentation helps ensure that information critical to the patient's continuing care is not disregarded. Documentation informs patient treatment and management and communicates this to other relevant staff so that they have this important data to consider when they are tasked with the patient's care. The record also serves to remind staff what has occurred so far in treatment, what has been helpful, and what interventions have not produced any meaningful results. Another important purpose of documentation involves administrative requirements, such as satisfying the requirements of various accrediting agencies and meeting the requirements of the correctional facility's administrative policies.

It is well known that post-suicide lawsuits account for the largest percentage of suits against psychiatrists (Baerger 2001; Packman et al. 2004). The American Psychiatric Association guidelines indicate that "Documenting the suicide assessment is essential" (APA 2003). Documentation is virtually always the centerpiece of post-suicide lawsuits. It is particularly critical to document the suicide risk assessment upon initial evaluation, significant changes in the patient's condition, or when there is a lack of improvement or worsening of the patient's condition. Risk assessment documentation should include some form of analysis of risk factors, and a general estimate of overall risk level (low, moderate, or high). This should be followed by a treatment plan (risk management plan as noted above) that directly addresses relevant dynamic risk factors, and the clinician's reasoning for choosing or rejecting options. When noting an action taken in furtherance of a risk management plan, it is essential to include a statement, however brief, of the rationale for the action. For example, the psychiatrist should document that he or she considered the option of inpatient hospitalization and the clinical basis for rejecting or proceeding with that option.

OTHER PREVENTION EFFORTS

Adequate correctional suicide prevention efforts go beyond screening and precautions for acute suicidal crises. Correctional administrators must develop and maintain comprehensive policies and practices (Hayes 2013). An array of programmatic interventions should be utilized, from immediate response to regular staff training and psychological autopsies of all fatalities by suicide. The immediate response to an inmate's suicidal cognitions or behavior should involve crisis intervention (Ivanoff and Hayes 2002). Crisis intervention procedures can be accomplished by both correctional and mental health staff. Crisis intervention consists of the following procedures carried out by trained correctional mental health staff: (1) establishing psychological contact with the inmate patient, (2) defining the precipitating problem, (3) encouraging exploration of the inmate patient's emotional conflict, (4) exploring and assessing past attempts to cope, (5) generating and examining alternative solutions, (6) taking action to restore cognitive and emotional functioning, and (7) dynamically reassessing suicide risk over time.

In terms of psychotherapeutic approaches, dialectical behavior therapy (DBT) has demonstrated effectiveness in reducing suicidal behavior in randomized clinical trials. DBT is a 1-year outpatient program composed of weekly group skills training and individual psychotherapy; however, modification may be made for specific correctional environments. Skills training targets include life-threatening behaviors, treatment-interfering behaviors, and quality of life behavior. Other skills commonly addressed include distress tolerance, emotion regulation, and interpersonal effectiveness. When compared to treatment as usual, DBT has shown significant decreases in suicidal behavior and self-mutilation. DBT has been modified for a correctional setting (DBT-Corrections Modified) and used to help inmate patients reduce impulsive–aggressive behaviors (Shelton et al. 2009).

In addition to the NCCHC recommendations for suicide prevention in corrections (http://www.ncchc.org/spotlight-on-the-standards-26-1), researchers have recommended the following prevention considerations (Patterson and Hughes 2008):

- Increased clinical monitoring of inmates in high-security units
- Follow-up monitoring regimens for suicidal inmates
- Group therapy for inmates in segregation who are on the mental health caseload
- Personal observation of inmates on suicide watch instead of video monitoring
- Improved CPR policy and practices
- Adequate confidential interviewing space
- Careful review of prior documentation by clinicians
- Timely completion of all documentation of the suicide assessment and management process

The NCCHC has recommended performing a review of all suicides as an important part of an overall suicide prevention program. In the authors' experience,

forward-thinking institutions have formed "suicide prevention improvement teams" consisting of representative staff from mental health, security, medical, administration, and quality improvement. The team meets on a regular basis to focus on identifying opportunities for change and improvement. Traditional efforts at suicide prevention have often focused on retrospective analyses of inmates' individual risk factors. However, a process improvement project conducted in the Connecticut Department of Corrections found that suicides often occur "due to poor communication of past information from community to the corrections department for non-sentenced inmates; inability to communicate events that occurred in court for sentenced inmates; inability to assess contradictions for restrictive housing in a thorough and timely manner; interruptions in the orientation process and improper housing of inmates" (Helfand and Trestman 2008). These experts recommended performing a "root cause analysis" after sentinel events, using the FMEA (Failure Mode and Effects Analysis) process as a guideline (http://www.isixsigma.com/dictionary/failure-mode-and-effects-analysis-fmea/).

Every correctional institution should have an adequate suicide risk assessment training program for all correctional staff. When this training is done in a systematic way, using evidenced-based methods, there is an increased likelihood of improved communication around suicide prevention issues, as well as improved risk assessment skills and documentation (McNiel et al. 2008).

CLINICAL CHALLENGES

Managing suicidal patients' risk is one of the most stressful endeavors a psychiatrist can face. The challenge may be more complex in correctional settings that are subject to limited resources and increasing numbers of individuals in the midst of acute life crises. Some of the more commonly seen challenges will be addressed here, and include the problems of inmate patient deliberate self-harm and "manipulative" suicide threats.

Deliberate self-harm and suicide risk

Self-inflicted injuries may occur with or without suicidal intent. The term *deliberate self-harm* (DSH) has been used to describe the willful self-infliction of painful, destructive, or injurious acts without the intent to die (American Psychiatric Association 2003). However, there is substantial definitional ambiguity surrounding the concept of DSH, and no universally accepted definition has been agreed upon (Mangnall and Yurkovich 2008). This may result in a confusion of synonyms, such as self-mutilation, parasuicide, and repetitive self-injury. Acts of DSH are considered to increase one's risk of suicide (Favazza 1998; Hawton et al. 2014). It is not possible to reliably distinguish patients who engage in self-harm from those who will ultimately commit suicide. The reasons for this are, in part, due to the dynamic and ambivalent nature of suicidal cognitions. For example, the individual may possess *both* the desire to self-harm *and* to commit suicide at the same time. Furthermore, the desire to self-harm may progress (either slowly or rapidly) to suicide. Indeed, an individual's suicidal intent may shift over time, which is why follow-up risk assessments are important. Finally, there is also the risk of accidental or miscalculated death while the individual engages in acts of self-harm.

Self-mutilation and suicide attempts cannot be easily differentiated, even in cases where the inmate is questioned about suicide intent (Konrad et al. 2007). Taking an unconcerned or punitive view of an inmate's DSH may increase risk by prompting the inmate to take increasingly more dramatic risks to communicate his or her problems. The detection of malingering among inmates whose external incentive may be to seek inpatient admission or psychiatric treatment is fraught with controversy and uncertainty. Even with the use of structured, objective tests for detecting malingering, there remains uncertainty, and clinicians are advised to remain "exceedingly cautious about assertions that individuals in …correctional settings are (or are not) feigning serious mental illness" given the rates of inaccuracy observed in well-designed studies (Edens et al. 2007).

There is a paucity of research on the prevalence of self-injurious behavior in corrections. A study of 51 state and federal prison systems found that a very small percentage (less than 2%) of inmates engage in self-injurious behavior each year. However, the acts occurred weekly in 85% of systems, disrupted correctional operations, and required a disproportionate amount of resources (Appelbaum et al. 2011). Self-injurious behavior in an inmate–patient can be very challenging to manage from both clinical and security standpoints. The behavior tends to raise concerns about suicide risk, personality disorder and manipulative intent. Thus, it is important to consider these possibilities very carefully before arriving prematurely at a conclusion of manipulative behavior or malingered suicidal intent.

Suicide attempts have been clearly shown to increase one's risk of ultimately dying from suicide. Although some studies have attempted to distinguish suicide attempters from suicide completers, correctional mental health staff would be ill advised to place too much weight on these findings in their clinical practice. There is no research to date suggesting that clinicians can reliably distinguish patients who use DSH as a form of "manipulation" from patients who pose a genuine suicide risk. The fact that both may be present, and that suicidal intent often shifts over time should suggest approaching this scenario with caution.

"Manipulative" is a popular but often misused description of behavior seen in some inmate patients who come to psychiatric attention. The literature suggests "that it would be a mistake to underestimate the risk of those with recent instrumental suicide related behavior, dismissing their behavior as manipulative or attention seeking" (Skeem et al. 2006). It is also important to keep in mind that "not

all low-lethality suicidal behaviors are meant to manipulate another person," and that "defining a behavior as manipulative impels distancing rather than greater understanding that the patient lacks necessary skills to gain a sense of control in nonmanipulative ways" (Berman 2006).

It is a well-known clinical phenomenon that some inmate–patients who engage in either DSH or various forms of self-mutilation do not suffer from suicidal cognitions at all; rather, they cut themselves as a way to cope, reduce their anxiety level, and/or focus on the sense of control that such acts provide. The challenge arises when mental health professionals seek to discern which of these individuals will go on to attempt suicide. An illustrative study was conducted in England and Wales over a period of 5 years (Hawton et al. 2014). It looked at incidents of self-poisoning or self-injury irrespective of degree of suicidal intent or underlying motive. Of 26,510 prisoners who engaged in such behavior, 109 subsequently died by suicide in custody, half of which occurred within 1 month of nonlethal self-harm. In male prisoners, the risk of suicide after self-harm was associated with older age as well as a previous self-harm incident of moderate or high lethality potential. In female prisoners, engaging in more than five incidents of DSH within a year was associated with subsequent suicide.

SUMMARY

Suicide prevention in corrections is a pressing mandate that requires reliable, evidence-based methods. Correctional suicide prevention goes far beyond clinical risk assessment and must involve facility-wide efforts at screening, training, communication, and policy review. The correctional environment creates special nuances that must be anticipated by the correctional mental health professional when conducting suicide risk assessments. Many correctional suicide risk factors are known and should be carefully considered during the suicide risk assessment process. The standard of care does not require the correctional mental health clinician to predict inmate patients' suicide. Rather, there is a general expectation by the courts that clinicians will use reasonable professional judgment, based on a thorough consideration of the clinical data and circumstances.

Successful correctional suicide prevention programs are a collaborative team effort, where correctional staff from multiple disciplines participate and give input to improve policies and procedures. Performing and documenting an adequate correctional suicide risk assessment will be likely to result in good psychiatric care, as well as protection from legal claims of negligence. Clinical efforts must be prioritized and supported by equally vigorous administrative and system-wide suicide prevention efforts.

The right to refuse treatment in a criminal law setting

MICHAEL L. PERLIN AND NAOMI WEINSTEIN

INTRODUCTION

The question of the right to refuse antipsychotic medication remains the most important and volatile aspect of the legal regulation of mental health practice (Plotkin 1977; Gelman 1984; Brooks 1987; Perlin and Cucolo 2016, §8-2; Perlin 2000). The issues that are raised—the autonomy of institutionalized individuals with mental disability to refuse the imposition of treatment that is designed (at least in part) to ameliorate their symptomatology; the degree to which individuals subjected to such drugging are in danger of developing irreversible neurological side effects; the evanescence of terms such as *informed consent* or *competency*; the practical and administrative considerations of implementing such a right in an institutional setting; and the range of the philosophical questions raised (dealing with autonomy, freedom, self-governance, and utilitarianism) (Perlin 1990; Perlin 1991; Perlin and Dorfman 1996; Perlin and Cucolo 2016, §8-2)—mark the litigation that has led to the articulation of the right to refuse treatment as "a turning point in institutional psychiatry" (Rhoden 1980) and "the most controversial issue in forensic psychiatry" (Brant 1983).

The conceptual, social, moral, legal, and medical difficulties inherent in the articulation of a coherent right to refuse treatment doctrine have been made even more complicated by the U.S. Supreme Court's reluctance to confront most of the underlying issues (*Mills v. Rogers* 1982). As a result of the court's decision in *Mills* (a case involving involuntarily committed civil patients) to "sidestep" the core constitutional questions (Wexler 1982; Perlin and Cucolo 2016, §8-5.8.1, 8-87), and its concomitant articulation of the doctrine that a state is always free to grant more rights under its constitution than might be minimally mandated by the U.S. Supreme Court under the *federal constitution* (*Mills v. Rogers* 1982, 300; Perlin 1987a), two parallel sets of cases have emerged.

In one set, state courts have generally entered broad decrees in accordance with an "expanded due process" model, in which the right to refuse treatment has been read broadly and elaborately, generally interpreting procedural due process protections liberally on behalf of the complaining patient. These cases have frequently mandated premedication judicial hearings, and have heavily relied on social science data focusing on the potential impact of drug side effects, especially tardive dyskinesia (e.g., *Rivers v. Katz* 1986; *Riese v. St. Mary's Hospital and Medical Center* 1987; *State ex rel. Jones v. Gerhardstein* 1987; Perlin 1991; *Virgil D. v. Rock County* 1994; Perlin and Dorfman 1996; Perlin and Cucolo 2016, §8-6.3.2; *Myers v. Alaska Psychiatric Institute* 2006). Some cases have begun to explore "second-generation" issues, such as the right to a jury trial in medication refusal hearings (e.g., *In re Brazleton* 1993; *People v. Fisher* 2009), whether a joint hearing on involuntary civil commitment and medication refusal is appropriate (e.g., *In re Barbara H.* 1998; *In re Dennis H.* 2002), or the application of the right in other settings such as juveniles in state care (e.g., *Matter of Sombrotto v. Christiana W.* 2008).

In the other set, federal courts have generally entered more narrow decrees in accordance with a "limited due process model." These provided narrower administrative review and rejected broad readings of the Fourteenth Amendment's substantive and procedural due process protections, relying less on social science data, which were frequently ignored or dismissed as part of an incomprehensible system allegedly beyond the courts' self-professed limited competency (e.g., *United States v. Charters* 1988; Perlin 1990, 1991; Perlin and Cucolo, 2016, §8-6.4). Generally (but not always), the state cases involved civil patients; more frequently, the federal cases dealt with individuals originally institutionalized because of involvement in the criminal trial process (Perlin 1991).

Although the Supreme Court has not dealt squarely with a civil right to refuse treatment case since its 1982 remand decision in *Mills*, it has since decided a case involving the rights of convicted prisoners to refuse medication (*Washington v. Harper* 1990; Perlin and Cucolo 2016, §8-7.1); one on the question of whether an insanity-pleading

defendant was denied a fair trial because he was involuntarily medicated at trial, thus depriving the jury of a fair presentation of his "natural demeanor" at the insanity stage (*Riggins v. Nevada* 1992; Perlin and Cucolo 2016, §8-7.2); and one on whether a state may involuntarily medicate a defendant in order to render him or her competent to stand trial (*Sell v. United States* 2003). These cases are discussed extensively in this chapter.

As this short overview should demonstrate, it is impossible to authoritatively articulate one doctrine to cover all rights to refuse treatment litigation. It is also impossible to state such a doctrine even for cases that arise in a "criminal law setting," because the simplest "unpacking" of that category (Perlin 1989–1990) reveals that there are at least seven major subcategories to which the right to refuse could be applied, to cases involving the following:

- Defendants awaiting incompetency to stand trial (IST) determinations
- Defendants found "permanently" IST in accordance with the Supreme Court's decision in *Jackson v. Indiana* (1972)
- Defendants otherwise awaiting trial in jails
- Defendants seeking to proffer a not guilty by reason of insanity (NGRI) defense
- Defendants who have been institutionalized following an NGRI finding
- Convicted defendants in prison
- Capital defendants whom state officials seek to medicate so as to make them competent to be executed
- Defendants committed as sexually violent predators

However, if each of these categories is considered briefly, it may better illuminate whether any strands of doctrinal coherency can be spelled out (cf. Perlin 1987b, 2000).

DEFENDANTS AWAITING TRIAL

Awaiting an IST determination

Prior to 1987, medication cases involving defendants awaiting IST determinations had "resulted in a series of apparently random decisions from which almost no doctrinal threads could be extracted," leading to "significant and genuine confusion" in this area (Perlin 1990, 963; Perlin 1989, §14.09; compare, e.g., *State v. Hayes* 1978 to *Whitehead v. Wainwright* 1978). Subsequently, though, two separate decisions in one case—with radically different opinions—have brought some measure of coherence to this area.

In 1987, a panel of the Fourth Circuit Court of Appeals issued the first decision in *United States v. Charters* (*Charters I*) on the right of a federal pretrial detainee to refuse psychotropic medication (*Charters* 1987). *Charters I* rejected the notion that the "exercise of professional judgment standard" (articulated by the Supreme Court in a case involving physical restraint of an individual with severe mental retardation [*Youngberg v. Romeo* 1982]) applied to antipsychotic medication cases, resurrected right-to-privacy and freedom-of-thought-process arguments that had been generally abandoned in the years since the Supreme Court's decision in *Mills v. Rogers*, established a right to be free from unwanted physical intrusion as an integral part of an individual's constitutional freedoms, and articulated a complex substituted judgment–best interests methodology to be used in right to refuse treatment cases (Perlin 1990; Perlin and Cucolo 2016, §8-5.6.1).

Upon an *en banc* rehearing, the full Fourth Circuit vacated the panel decision (*Charters* 1988) (*Charters II*), "suggesting that the panel was wrong, about almost everything" (Perlin 1990, 965). Although it agreed that the defendant possessed a constitutionally retained interest in freedom from bodily restraint that was implicated by the forced administration of psychotropic drugs, and the defendant was protected "against arbitrary and capricious action by government officials" (*Charters II* 1988, 306), it found that informal institutional administrative procedures were adequate to protect the defendant's due process interests. It applied the "substantial professional judgment" test of *Youngberg*, and limited questioning of experts to one matter: "Was this decision reached by a process so completely out of bounds as to make it explicable only as an arbitrary, nonprofessional one?" (*Charters II* 1988, 313; Perlin and Cucolo 2016, §18-3.2, 18-46).

The two views of the rights of pretrial detainees to refuse medication reflected in *Charters I* and *Charters II* could not be more diametrically opposed. Also, the ultimate *en banc* decision has led to some important strategic decision making for attorneys representing individuals who wish to resist the imposition of such medication. Although, as a federal detainee, Charters was forced to litigate in federal court, in cases where litigants do have an option of availing themselves of a state forum, the second *Charters* decision made it more likely they will choose the latter jurisdictional alternative. When *Charters II* was decided, it was seen to potentially "signal the death knell for the litigation of right-to-refuse treatment issues in the federal forum" (Perlin 1990, 994) in cases in which litigants retain discretion as to where to sue. In the immediate following years, at least two state courts—albeit in civil cases—adhered to their endorsements of *Charters I* even *after* the *Charters II* decision (e.g., *McConnell v. Beverly Enterprises-Connecticut, Inc.* 1989; *In re A. C.* 1990; Perlin and Cucolo 2016, §18-3.2); but, several post-*Charters II* state cases have not granted defendants broader rights in similar cases (e.g., Perlin and Cucolo 2016, §18-6, 18-64; *State v. Otero* 1989; *People v. Lopez* 1990).

Subsequently, the Sixth Circuit has held that the "strict scrutiny" standard of substantive due process review applied to this question (see e.g., Perlin 1993–1994; Perlin 1997), finding that the government must prove its case by clear and convincing evidence (*United States v. Brandon* 1998). The Second Circuit has held in *United States v. Gomes* that, as the "heightened scrutiny standard" was appropriate for determining when a nondangerous criminal defendant could be forcibly medicated with antipsychotic drugs

for the purpose of rendering him competent, a four-part test was needed:

> We think that the government must show, and the district court must explicitly find, by clear and convincing evidence (1) that the proposed treatment is medically appropriate, (2) that it is necessary to restore the defendant to trail competence, (3) that the defendant can be fairly tried while under medication, and (4) that trying the defendant will serve an essential government interest. (*United States v. Gomes* 2002, 82)

The court stressed that the process of medicating a defendant is a "dynamic one" that can be evaluated over the course of treatment "to ascertain, with expert assistance, both its effectiveness and the nature of any side effects" (p. 82). In reaching its determination, the court looked closely at "recent advances in antipsychotic medication" that "reduce our concerns that the defendant's health interests and fair trial rights cannot be adequately protected when he is involuntarily medicated to render him competent to stand trial" (p. 83).

In 2003, the Supreme Court directly addressed the issue of whether a state may involuntarily medicate a defendant to render him or her competent to stand trial, holding that when a mentally ill defendant faces serious criminal charges, the government may only involuntarily administer antipsychotic drugs if the treatment was medically appropriate, substantially unlikely to have side effects that may undermine the trial's fairness, and necessary to significantly further important governmental trial-related interests (*Sell v. United States* 2003). In reaching its conclusion, the court recognized that under *Washington v. Harper* (1990) and *Riggins v. Nevada* (1992) Sell had a liberty interest in avoiding the involuntary administration of antipsychotic drugs, and this interest was protected by the Fifth Amendment's due process clause against all but "essential" or "overriding" state interests (p. 179).

Sell is an extremely important decision for several reasons. First, it elevates much of Justice Kennedy's concurring opinion in *Riggins* (see below) to majority status. Second, the decision italicizes many important phrases like "*important* governmental interests," "*significantly further* concomitant state interests," that involuntary medication is *necessary* to further those interests, that administration of the drugs in *medically appropriate,*" emphasizing the importance of these issues to the court. Third, the court stresses the need to engage in a "least restrictive alternative" analysis in every such case. By way of example, the Ninth Circuit held that due process did not require the Bureau of Prisons to specify the medication before it could involuntary medicate a defendant (*United States v. Loughner* 2012). Finally, in its discussion, the court makes clear that decisional incompetence and current danger are the only two acceptable overrides in civil cases (Perlin and Cucolo 2016, §8-7.3.2). Also, it needs to be stressed that all circuits that have considered this issue post-*Sell* have concluded that the government bears the burden of proof in such cases by clear and convincing evidence (see, e.g., *United States v. Bradley* 2005; *United States v. Grape* 2008; citing *United States v. Bush* 2009; *United States v. Ruiz-Gaxiola* 2010).

But, notwithstanding *Brandon, Gomes*, and *Sell* (and other post-*Charters* federal cases rejecting its methodology; see e.g., *Preston v. Gutierrez* 1993; *Kulas v. Valdez* 1998; *United States v. Weston* 2000), the second Fourth Circuit decision in *Charters* remains important "jurisprudentially, constitutionally, and symbolically" (Perlin 1999, §3B-8.1b, 312). The individual's interests in refusing treatment with antipsychotic medications is arguably greater in the pretrial context because the defendant has an interest not only in avoiding unintended side effects, but also in avoiding what may be potentially legally prejudicial effects of medication (Dlugacz and Wimmer 2013). This makes cases like *Brandon, Gomes*, and *Sell*, even more important jurisprudentially and constitutionally.

DEFENDANTS PERMANENTLY IST

In *Jackson v. Indiana*, the Supreme Court held that it violated due process to commit an individual for more than the "reasonable period of time" necessary to determine "whether there is a substantial chance of his attaining the capacity to stand trial in the foreseeable future" (*Jackson* 1972, 733). If there were to be no such chance, a defendant originally committed pursuant to an IST finding would either be subjected to the civil commitment process or released; once having been "Jacksonized" (that is, having had his or her criminal indictments dismissed but remaining in need of hospitalization), such a patient must be treated like other civil patients (Perlin 1991). However, a recent study indicates that nonrestorable "*Jacksonized*" committees are often treated differently once committed than "regular" civil commitment patients (Levitt et al. 2010), being subject to more involuntary medication; further this cohort of patients was less likely to meet usual statutory commitment criteria (Levitt et al. 2010).

There has been virtually no case law on the rights of "Jacksonized" patients to refuse medication; none of the three pertinent cases substantially illuminates the underlying doctrinal issues (*DeAngelas v. Plaut* 1980; *Mannix v. State* 1981; *Woodland v. Angus* 1993; Perlin and Cucolo 2016, §8-7.5.2). *Charters II* and *Sell* should not have a significant impact on this population, who should be treated like other civil patients (due to the dismissal of the underlying indictments that triggered their entry into the criminal trial process). Thus, it can be expected that future developments here will track similar developments involving involuntarily committed civil patients (Perlin 1991), and will more closely adhere to the "expanded due process" model. A recent comprehensive state-wide study has concluded that "too many people found not competent to stand trial are [still] unnecessarily locked in a secure setting for

treatment and, on average, are confined for longer periods than research demonstrates is clinically reasonable" (Justice Policy Institute 2011).

OTHERWISE AWAITING TRIAL IN JAILS

Cases involving jailed pretrial detainees have generally interpreted the right to refuse treatment broadly. In *Bee v. Greaves*, the Tenth Circuit ruled that "less restrictive alternatives" should be ruled out before psychotropic medication is involuntarily administered to a jailed detainee (*Bee* 1984, 1396; Perlin and Cucolo 2016, §8-6.3.3); other courts have similarly ruled that the availability of a less intrusive alternative that could have been employed by defendants must be considered in the determination of such a case (*Osgood v. District of Columbia* 1983; *Harrison v. State* 1994; *State v. Kotis* 1999; Perlin and Cucolo 2016, §8-6.3). Later, courts have also chosen to follow the holding of *Sell* and apply it to pretrial detainees (*In re Mark W* 2004).

DEFENDANTS PLEADING INSANITY

At trial

In *Riggins v. Nevada*, the U.S. Supreme Court reversed the decision of the Nevada Supreme Court (on the involuntary administration of medication to a defendant at trial), holding that the use of antipsychotic drugs violated the defendant's right to fair trial (*Riggins* 1992; Perlin and Cucolo 2016, §8-7.2). The court cited language from its previous opinion in *Washington v. Harper* (1990) regarding the impact of drug side effects on constitutional decision making, and construing *Harper* to require "an overriding justification and a determination of medical appropriateness" prior to forcibly administering antipsychotic medications to a prisoner (*Riggins* 1992, 134–135).

The *Riggins* Court focused on what might be called the "litigational side effects" (Perlin 1994c, 251) of antipsychotic drugs, and discussed the possibility that the drug use might have "compromised" the substance of the defendant's trial testimony, his interaction with counsel, and his comprehension of the trial (*Riggins* 1992, 137). In a concurring opinion, Justice Kennedy (the author of *Harper*) took an even bolder position. He would not allow the use of antipsychotic medication to make a defendant competent to stand trial "absent an *extraordinary* showing" on the state's part, and noted further that he doubted this showing could be made "given our present understanding of the properties of these drugs" (*Riggins* 1992, 139).

Justice Thomas dissented, suggesting that (a) the administration of the drug might have *increased* the defendant's cognitive ability; (b) since Riggins had originally asked for medical assistance (while a jail inmate, he "had trouble sleeping" and was "hearing voices"), it could not be said that the state ever "ordered" him to take medication; (c) if Riggins had been aggrieved, his proper remedy was a §1983 civil rights action; and (d) under the majority's language, a criminal conviction might be reversed "in cases involving…penicillin or aspirin" (*Riggins* 1992, 150–155).

Riggins is the Court's most expansive reading of the effect of psychotropic drugs' side effects on an individual's functioning (Perlin 1999, §3B-8.3). Justice Kennedy's concurrence highlights the ways that such side effects could imperil a fair trial:

> Behavior, manner, facial expressions, and emotional responses, or their absence, combine to make an overall impression on the trier of fact, an impression that can have a powerful influence on the outcome of the trial. If the defendant takes the stand, as Riggins did, his demeanor can have a great bearing on his credibility, his persuasiveness, and on the degree to which he evokes sympathy. (*Riggins v. Nevada* 1992, 142)

This is the clearest articulation of this position in any opinion by any Supreme Court justice.

Kennedy's observations as to jurors' responses to defendants who fail to display the proper "remorse and compassion" is also telling:

> The prejudice can be acute during the sentencing phase of the proceedings, when the sentencer must attempt to know the heart and mind of the offender and judge his character, his contrition or its absence, and his future dangerousness. In a capital sentencing proceeding, assessments of character and remorse may carry great weight and, perhaps, be determinative of whether the offender lives or dies. (Ibid., 144)

Kennedy's reliance here on a law review article that reports on the experiences of real jurors in real cases (Geimer and Amsterdam 1987) reflects an important sensitivity to the ways that jurors process clues and cues about the *persona* of capital defendants, and his integration of that data into an analysis of the ways that jurors may potentially respond to medicated defendants demonstrates a similar sensitivity to the way that visual images of mentally disabled defendants may be dispositive of juror decision making on this question.

Justice Thomas's opinion raises grave issues for defense counsel (Perlin 1994a, 2000). Had his position prevailed, would concerned and competent defense lawyers feel as if they were assuming a risk in *ever seeking* psychiatric help for an awaiting-trial defendant (Perlin 1992)? His analogizing of antipsychotic drug side effects to penicillin or aspirin may be disingenuous, or it may be cynical. What is clear is that nowhere in the lengthy corpus of right to refuse treatment litigation is this position ever seriously raised (Perlin and Dorfman 1993; Perlin and Cucolo 2016, §8-7.2, 8-164).

Following an NGRI verdict

While individuals who had been previously adjudicated NGRI were members of some early class actions challenging institutional drugging practices (e.g., *Davis v. Watkins* 1974; compare *Rennie v. Klein* 1979; *Davis v. Hubbard* 1980), there has been remarkably little litigation on behalf of this population (Perlin 1991, 47). The most important case, a Maryland state decision, construed a U.S. Supreme Court case that limits the treatment refusal rights of *prisoners* (*Washington v. Harper* 1990) to guard against the arbitrary administration of antipsychotic drugs in the context of NGRI insanity acquittees, and declared unconstitutional a state statute that failed to provide such a patient with the rights for adequate notice, to be present, to present evidence, and to cross-examine witnesses at a drug refusal hearing, and to have the right to judicial review of an adverse decision at such a hearing (*Williams v. Wilzack* 1990). *Williams*, which relied on both state and federal constitutions, thus suggests that lower courts may limit *Harper* to the specific population in that case (convicted prisoners), even where the patient's original confinement stems from the criminal trial process (Perlin and Cucolo 2016, §8-7.5.3, 8-186 to 8-187).

More recently, a federal district court in Wisconsin struck down that state's statute governing the administration of antipsychotic medication to insanity acquittees, finding the law unconstitutional because it did not require the court to make a determination that the incompetent insanity acquittee was dangerous and that the medication was in his best interests (*Enis v. Department of Health and Social Serv.* 1996). On the other hand, the California Court of Appeals has held that an insanity acquittee was not entitled to a hearing on his competence to refuse antipsychotic medications (*In re Locks*, 2000).

CONVICTED PRISONERS

The Supreme Court's decision in *Harper* sharply limited the right of convicted felons to refuse treatment under the federal constitution. (For pre-Harper cases brought under constitutional law theories, see, e.g., *Keyhea v. Rushen* [1986]; *Large v. Superior Court* [1986].) While the court agreed that prisoners (like all other citizens) possessed a "significant liberty interest" in avoiding the unwanted administration of antipsychotic drugs (*Harper* 1990, 221, quoting *Vitek v. Jones* 1980, pp. 488–491), it found that the need to balance this interest with prison safety and security considerations would lead it to uphold a prison rule regulating drug refusals as long as it was "reasonably related to legitimate penological interest," even where fundamental interests were otherwise implicated (*Harper v. Washington* 1990, 222). Thus, a state policy—that provided for an administrative hearing (before a tribunal of mental health professionals and correctional officials) at which there was neither provision for the appointment of counsel nor regularized external review—passed constitutional muster (*Harper* 1990, 223–224).

In a sharply worded opinion, Justice Stevens dissented, arguing that the refusal of medication was "a fundamental liberty interest deserving the highest order of protection," especially where the imposition of such medications might create "a substantial risk of permanent injury and premature death" (*Harper* 1990, 237). But *Harper* clarifies an important strand of Supreme Court jurisprudence: "Prison security concerns will, virtually without exception, trump individual autonomy interests" (Perlin 1999, §3B-8.2, 320).

Post-*Harper* cases have construed the decision in a wide variety of substantive and procedural contexts, with some courts relying on it to order full hearings on right-to-refuse claims, and others citing it to limit the scope of the applicant's right to refuse (Perlin and Cucolo 2016, §8-7.1, 8-156 to 8-158, and cases cited at note 1229). Moreover, although the trend has been slowed down by the Supreme Court's subsequent decision in *Riggins v. Nevada* (1992), *Harper* was the first Supreme Court case to "point…claimants to the state court door, and steer…them away from federal courts" (Brian 1992, 282).

The interplay between *Harper* and *Sell* was addressed in *United States v. Kourey* (2003). There, the court denied the prison officials' application for forced medication, brought pursuant to *Sell*, on the basis that *Sell* was inapplicable because the offense was not a serious offense, the prison had not gone through a *Harper* proceeding that might present alternative grounds related to the individual's dangerousness or the individual's own interests where refusal to take drugs puts his health gravely at risk, and that the defendant had not been formally adjudicated incompetent.

COMPETENCY TO BE EXECUTED

Still undecided is the important question of whether a state can involuntarily medicate an individual under a death sentence so as to make him or her competent to be executed. After the Supreme Court determined that an incompetent defendant with mental illness cannot be executed (*Ford v. Wainwright* 1986) (a holding that was extended to cases involving individuals with mental retardation in *Atkins v. Virginia* 2002, which effectively overruled the court's earlier decision in *Penry v. Lynaugh* 1989, and which was later clarified and expanded on in *Hall v. Florida* 2014), it initially agreed to hear a case that posed this precise question (*Perry v. Louisiana* 1990a).

In *Perry*, the Louisiana state courts had found that any due process right the capital defendant might have was outweighed by two compelling state interests: the provision of psychiatric care, and the carrying out of a valid death penalty (*State v. Perry* 1989). After the Supreme Court originally decided to hear the case (to determine whether the Eighth Amendment's proscription against cruel and unusual punishment prohibits states from so medicating death-row inmates; *Perry* 1990a), it ultimately vacated the lower court's decision and remanded for further proceedings in light of its decision in *Harper* on the scope of a convicted prisoner's right to refuse (*Perry v. Louisiana* 1990b).

The Supreme Court's reasoning in this case is not clear. It may be that the justices felt, upon reflection, that the only issue presented was that of forcible medication (finding the execution consequences irrelevant), and it was thus necessary for the state court to consider, after *Harper*, whether the difference in long-term harm in a case such as *Perry* (his execution) outweighed the state's interest in involuntarily medicating him (Perlin and Cucolo 2016, §17-5; "Supreme Court Sidesteps Issue" 1990). Interestingly, the Supreme Court had decided *Harper* a week *before* it chose to grant *certiorari* in *Perry*; its decision to vacate and remand for consideration of *Harper* may thus mean that the court could not—or would not—resolve the difficult tensions presented by such a case (Perlin 1994b).

On remand, the Louisiana Supreme Court found, under *state* constitutional law, that the state was prohibited from medicating Perry to make him competent to be executed. The court concluded:

> For centuries no jurisdiction has approved the execution of the insane. The state's attempt to circumvent this well-settled prohibition by forcibly medicating an insane prisoner with antipsychotic drugs violates his rights under our state constitution. … First, it violates his right to privacy or personhood. Such involuntary medication requires the unjustified invasion of his brain and body with discomforting, potentially dangerous and painful drugs, the seizure of control of his mind and thoughts, and the usurpation of his right to make decisions regarding his health or medical treatment. Furthermore, implementation of the state's plan to medicate forcibly and execute the insane prisoner would constitute cruel, excessive and unusual punishment. This particular application of the death penalty fails to measurably contribute to the social goals of capital punishment. Carrying out this punitive scheme would add severity and indignity to the prisoner's punishment beyond that required for the mere extinguishment of life. This type of punitive treatment system is not accepted anywhere in contemporary society and is apt to be administered erroneously, arbitrarily or capriciously. (*State v. Perry* 1992, 747–748)

The Supreme Court subsequently denied *certiorari* in *Singleton v. Norris* (2003), a case where the Eighth Circuit denied a writ of *habeas corpus* seeking a stay of execution for an inmate who had regained competency as the result of forced antipsychotic medication. In reaching its determination, the Eight Circuit noted that it was guided by both *Harper* and *Ford* and its task was to weigh the state's interest in carrying out a lawfully imposed sentence against Singleton's interest in refusing medication. The court rejected Singleton's claim, based on *State v. Perry*, that the Eighth Amendment prohibited execution of one who is made "artificially competent" (p. 1027). Several years later, in *Panetti v. Dretke*, the Fifth Circuit found that a medicated defendant was competent to be executed. The Fifth Circuit affirmed the decision of the district court finding that, although the defendant suffered from schizoaffective disorder, and had a "delusional belief system in which he viewed himself as being persecuted for his religious activities and beliefs," the defendant was aware that he was to be executed and that he committed murders. The Supreme Court granted *certiorari* and ultimately reversed, holding that the defendant was denied constitutional procedures to which he was entitled under *Ford* (*Panetti v. Quarterman* 2007). However, in *Panetti,* the court did not discuss the issue of involuntary medication (Perlin 2010).

The Supreme Court has not yet directly revisited this question, but it can be expected that the question will inevitably arise again in the future, and that the court will have yet another chance to weigh the competing values (Perlin and Cucolo 2016, §17-4.1.6).

DEFENDANTS COMMITTED AS SEXUALLY VIOLENT PREDATORS

The Wisconsin Supreme Court has ruled that the rights and procedures for the involuntary administration of antipsychotic medication established in the state mental health code apply to sex offenders involuntarily committed as sexually violent persons (*State v. Anthony* D.B. 2000).

By contrast, a California appeals court held that competent committees under the Sexually Violent Predator Act (SVPA) could be involuntarily medicated in nonemergency circumstances as long as the medication was used for therapeutic and not punitive reasons (*In re Calhoun* 2003). The court found that commitment under SVPA "impliedly authorized" such involuntary treatment, because commitment as an SVP required a judicial determination that the individual had a mental disorder that rendered him a danger to others (p. 52). The court rejected arguments that involuntary medication of competent committees violated federal due process rights and state constitutional privacy rights.

INTERNATIONAL LAW AND THE RIGHT TO REFUSE TREATMENT

International standards concerning involuntary medication of criminal defendants and prisoners set a higher bar for medication of inmates (Dlugacz and Wimmer 2013). The Convention on the Rights of Persons with Disabilities (CRPD), to which the United States is a signatory, but has yet to ratify, requires that states recognize that persons with disabilities enjoy legal capacity on an equal basis with others. The CRPD is "regarded as having finally empowered the 'world's largest minority' to claim their rights, and to participate in international and national affairs on an equal basis with others who have achieved specific treaty

recognition and protection" (Kayess and French 2008, 4). Article 25(d) of the CRPD addresses informed consent and requires health professionals to "provide care on the basis of free and informed consent by, inter alia, raising awareness of the human rights, dignity, autonomy and needs of persons with disabilities through training and the promulgation of ethical standards for public and private health care." Article 14.2 of the CRPD extends the rights it guarantees to those incarcerated or awaiting trial on an equal basis.

SUMMARY

This issue remains one of the most volatile areas of mental disability law. The decisions in *Charters II* (1988) and *Harper* (1990) had made it appear that the federal courts would no longer be the voluntary forum of choice for persons seeking to assert their right to refuse medication. The Supreme Court's decision in *Riggins* (1992) and *Sell* (2003), however, made it appear as if the federal forum would not necessarily be a hostile one for plaintiffs bringing such actions. Post-*Riggins* and post-*Sell* cases have been brought in both state and federal forums and, although results have been mixed, it can now be said that the complete exodus to state courts—predicted following the *Charters* and *Harper* decisions—has been halted, and that *both* state and federal courts now remain responsive to right to refuse medication actions (Perlin 1999, §3B-8.4, 330). The growing conservatism of the federal judiciary will most likely result in more affirmative litigation being brought in state courts based on state constitutional theories. Many state courts appear willing to consider carefully the arguments of plaintiffs in right to refuse cases brought by individuals in the criminal trial process.

It is necessary that the precise status of the patient—e.g., jail detainee, prisoner, insanity acquittee; *Jacksonized* permanently incompetent—be "unpacked" so as to "decode" the operative, controlling legal principles (Perlin 1991). If this is done, it is possible that some harmony might be brought to this most contentious area of litigation (Gelman 1983–1984, 122) and that the dilemma at the heart of the controversy—"preserving patient dignity while maintaining allegiance to treatment needs" (Roth 1986, 161)—might yet be resolved.

Hunger strikes by inmates

GEORGE DAVID ANNAS

INTRODUCTION

A hunger strike, while passive in nature, is one of the most dramatic forms of protest that a human being can express. Such an action comes about as a last resort when one has no other peaceful means of protest remaining and is willing to die for the cause at hand. The act has been carried out in human culture since the beginning of recorded history, examples include the text of one of the oldest epic poems, the Hindu *Ramayana,* dating somewhere from 500 to 200 BCE (Chaurasia 2002), and Ancient Rome (Simanowitz 2012). As a testament to how powerful the act can be, it is notable that some hunger strikers changed history with their protest. Famous cases include those of Mahatma Ghandi, Hugo Chavez, and the pioneers of the women's Suffrage movement.

In addition to hunger strikes that have occurred in free society, this practice occurs routinely among the incarcerated. One well-known hunger strike occurred in 1981 among Provisional Irish Republican Army (IRA) prisoners at the Maze Prison in Northern Ireland, which led to the starvation deaths of 10 IRA members (BBC 2015). Yet examples of hunger strikes among the incarcerated have been documented as far back as the first century AD, when Aulus Cremutius Cordus, a Roman historian, starved himself to death during his confinement (Coleman 2013).

When the lack of autonomy of the incarcerated individual is considered, the logic of the hunger strike becomes perceptible. One of the few things a prisoner can exert control over is choosing not to eat. The precise frequency of hunger strikes in corrections is unknown as little data exist. In addition, the U.S. Department of Justice's (DOJ) Bureau of Justice Statistics (BJS) does not keep records on their incidence or prevalence.

Studies in the United Kingdom suggest that hunger strikes are infrequent, there is no apparent correlation between the type of crime and food refusal, and motives caused by anorexia nervosa are rare (Larkin 1991). In addition, protests of a personal injustice were more likely to motivate longer fasting, but overall weight loss was not substantially different between those groups and other strikers (O'Connor and Johnson-Sabine 1988).

Data regarding the prevalence of mental illness among correctional hunger strikes (as well as the potential impact of said mental illness on capacity) are similarly sparse. The studies mentioned above suggested an association between mental illness and hunger strikes, but had little information regarding decision-making capacity among mentally ill hunger strikers. Another UK study noted a low prevalence of mental illness motivating a hunger strike (Brockman 1999). This chapter will address the issue of hunger strikes in correctional settings, the role a forensic psychiatrist may play in their assessment and management, the unique aspects of assessing competence to engage in a hunger strike, and the ethical dilemmas that can arise in these situations. For simplicity I will use the term "prisoner" and the male gender when discussing hunger strikes in this chapter, with the understanding that they can take place in any correctional setting and among both men and women.

HUNGER STRIKE DEFINITION

What is a hunger strike? It is not a simple task to cleanly answer this question. The World Medical Association (WMA) in its Declaration of Malta on Hunger Strikers, states, "A hunger striker is a mentally competent person who has indicated that he has decided to embark on a hunger strike and has refused to take food and/or fluids for a significant interval" (1991, 1992). This definition indicates perhaps the most important aspect of one engaging in a hunger strike—competence. The International Committee of the Red Cross (ICRC) defines a hunger strike as "voluntary fasting pursued for a specific purpose" (Reyes 1998). The ICRC definition indicates another important aspect in addition to competence, that of the striker expressing a specific purpose. The word "voluntary" denotes *de facto* competence, as well as indicating that such an act should only be considered a hunger strike if it is free from coercion.

Perhaps the multiple definitions of hunger strike are suggestive of the complexity of the phenomenon. The Federal

Bureau of Prisons (BOP) defines a hunger strike as occurring when the prisoner "communicates that fact to staff and is observed by staff to be refraining from eating for a period of time, ordinarily in excess of 72 hours" or "when staff observe the inmate to be refraining from eating for a period in excess of 72 hours" (Lappin 2005). The California Department of Corrections and Rehabilitation (CDCR) defines a hunger strike as an inmate missing nine consecutive meals (2013). Other definitions focus on the length of time someone refuses food and determines the initial intervention at that point—usually a medical examination. The problem with the common definition used by correctional facilities is that neither competence nor a stated purpose is routinely addressed prior to using the label.

Despite the fact that one can encounter any combination of factors, stated purposes, and degrees of mental capacity, the ICRC definition of a hunger strike (i.e., a competent individual refusing food for a stated purpose) provides a straightforward and rational guideline to use when attempting to differentiate between one who simply stops eating for any reason, and one who is engaging in a hunger strike. As demonstrated later in this chapter, keeping such a definition in mind can help guide an evaluating psychiatrist toward a valid assessment and beneficial contribution to the team charged with managing the welfare of the prisoner.

One often encounters the term "Hunger Strike" whenever a prisoner refuses food, likely based on the definitions put forth by correctional institutions. Such a liberal use of the term may simply lead to confusion. For example, consider the case of an inmate who was depressed and had refused food with the intent to die (Associated Press 2014). Such an individual whose mental illness led to suicidal intent should not be considered by any mental health or correctional professional as having been on a hunger strike, because he is not likely to be acting autonomously, raising critical issues of competence and need for medical and legal intervention.

Other terms may be helpful to further qualify a hunger strike. A hunger striker who refuses all food and all fluids is referred to as a "dry hunger striker," while one who refuses food but accepts some form of liquid intake supplement is considered a "total hunger striker" or engaging in a "voluntary total fast" (Reyes et al. 2013). Those who refuse both food and all fluids may be doing so in a reactionary way with no intention of continuing and therefore no risk of death by starvation (Reyes 1998), or do so when driven by significant mental illness or mental defect (Larkin 1991). The true hunger striker's goal is to have his demands met; therefore, the goal is to prolong a fast as long as possible; the goal is not death. Yet the hunger striker may be prepared to die, if necessary (WMA 2006).

It is logical to conclude that, in some cases, a consulting psychiatrist will not be able to determine if a fasting prisoner is on a hunger strike or not, until an assessment for capacity is performed. The psychiatrist may find himself or herself in many potential roles, however, both during and after the assessment is performed.

PSYCHIATRIC EVALUATION OF HUNGER STRIKES

The consult

Depending on the situation, a forensic psychiatrist who does not work for the correctional facility may be independently asked to evaluate a prisoner for competence to engage in a hunger strike (such as by the prisoner's attorney, the judge, or the correctional facility). Although not eliminated altogether, the risk of institutional bias is lessened in these situations. A potential disadvantage in these cases may be the timing of the evaluation. Although the consulting psychiatrist will likely have little control in this regard, the time that it takes an institution to set up an evaluation by an outside consultant may delay the evaluation to the point where an otherwise competent hunger striker may appear less so upon examination (Birchard 1997).

As with any psychiatric consultation, it is vital to determine with the requesting entity the specific and appropriate question(s) to address. Such questions may include the following: "Does the prisoner have the capacity to engage in fasting?" or "Does the prisoner have a mental illness and, if so, does the mental illness impair the decision-making capacity of the prisoner in regard to a hunger strike?" Less sophisticated questions may be encountered, such as "is the prisoner a true hunger striker?" However, it is important to avoid labels that may insult a reactive prisoner and lead to a detrimental "power of wills" (Reyes 1998).

Should the question involve recommendations about management as well, the wording of the question may be even more important. For example, it would be reasonable and appropriate to answer questions regarding recommendations for management of a fasting prisoner with a mental illness who has been opined to be incompetent by the examiner. However, if one is asked "do you recommend force-feeding," this would not be appropriate to address. Regardless of the final opinion on capacity or the final adjudication of such, force-feeding is widely recognized as unethical, and efforts should be made to prevent its practice (WMA 1991–1992, 2006; see also Legal and Ethical Issues in Managing a Hunger Strike, below). The correctional institution may frame the scenario as "either the prisoner starts eating again or we will have to force feed him." However, the psychiatrist should be mindful to avoid falling into the trap of this false dichotomy.

An ethical ban on force-feeding does not preclude the potential necessity for artificial feeding in an emergent situation if an incompetent prisoner prolongs a fast, putting his life at risk. But the important point is that there are other interventions that should be attempted first in situations where food refusal is deemed to be secondary to a mental illness and not a competent protest decision (see below, Management of the Incompetent Fasting Prisoner). When these avenues are taken, the dilemma is often moot (Reyes 1998).

Whether in a correctional treatment or an independent consultant setting, forensic psychiatrists possesses specialized expertise that is helpful in the situations where a prisoner begins to consistently refuse food. This may include educating the prisoner and medical team about possible mental status changes that will be expected during starvation, educating the team about how the personality structure of the prisoner may affect his or her behavior, as well as using the knowledge of interpersonal team dynamics to prevent or minimize negative staff countertransference reactions during the management of hunger strikes.

EVALUATION OF COMPETENCE

When a forensic psychiatrist is asked to form an opinion on the prisoner's competence to engage in a hunger strike, much of the approach is similar to that of assessing one's capacity to make treatment decisions. However, there are a few aspects of this evaluation that are unique. Unlike someone refusing artificial feeding (which would require a medical procedure and therefore constitute a refusal of treatment), someone refusing food is refusing basic nourishment that we all engage in daily in order to continue living. One's competence *to* eat is never questioned, and unlike refusing a medical intervention that may or may not result in death, ultimately starvation always will.

Prior to evaluating the prisoner's competence, pre-evaluation preparation is necessary. The following recommendations for preparation are based on the author's experience, as well as the relevant literature applied to hunger strikes:

- Meet with treatment staff regarding concerns, prisoner's condition, prognosis, and interventions utilized
- Review the prisoner's medical and psychiatric history, lab results, and relevant studies
- Review any past hunger strikes by the prisoner and their outcomes
- Review any recent emergency treatment orders and why given (Kim 2010)

A widely accepted model for approaching the evaluation of competence to make treatment decisions has been developed by Grisso and Appelbaum (1998). They write that an approach to assessing competence to accept or refuse treatment should address the domains of communicating choices, understanding relevant information, appreciating the situation and consequences, and manipulating information rationally. In addition, they note the importance of evaluating for psychopathology and taking into consideration context and personal behaviors (1998). Some of these items are addressed below in the context of evaluating capacity to engage in a hunger strike.

Communicating choices

This aspect of competence rarely would become an issue with a hunger striker. If someone is not consistent in regard to refusing meals, it will be unlikely to lead to a life-threatening situation. Furthermore, a psychiatrist would rarely be called in until someone began stopping meals consistently.

Understanding relevant information and appreciating the situation and consequences of fasting

Although it would be rare that someone would not know that the ultimate consequence of fasting is death (and if he did not, it would be rare that he was competent), an adequate demonstration of understanding goes beyond this. It is important that he be able to demonstrate knowledge of the relevance of pre-existing medical conditions that might risk permanent injury sooner that one might expect. For example, for a prisoner with a stomach ulcer it is important that he be able to demonstrate the understanding that the dangers of an ulcer (relevant facts) pertain to him (his situation) and may put him at risk for internal bleeding early on during the fast (consequences). A prisoner with bipolar disorder may understand the basic facts in regard to prolonged fasting leading to death, but voice the opinion that he is invincible and therefore such a rule of nature did not apply to him (i.e., failure to understand one's situation and consequences, despite the ability to understand relevant information).

Another aspect of appreciating one's situation and consequences include his perceived expectation about what he will accomplish with his strike. This brings up an important and related aspect of the evaluation—the stated reason for the hunger strike, which also touches on the ability to rationally manipulate information to come to the decision to engage in a hunger strike.

Manipulating information rationally

One of the most vital aspects of an evaluation for competence to engage in a hunger strike involves eliciting the stated reason for the strike. For example, a prisoner stating that he is fasting in order to rid the body of demonic spirits may indeed lack the ability to engage in a rational process of decision making about refusing nutrients. But like one's competence to refuse treatment, a stated purpose that appears illogical may not necessarily imply a lack of competence. In the absence of significant impairment in other domains, this aspect of the evaluation may be as simple as the prisoner being able to demonstrate that the strike is a form of protest that is meant to bring about some goal, assuming the goal is not incoherent or bizarre.

A prisoner who decides to fast in order to protest the United States' involvement in a foreign war may sound irrational. However, the stated purpose, itself, would not alone imply a lack of competence. The importance of this aspect of the evaluation is the person's rational manipulation of information to reach the decision—the latter of which, in itself, may not be required to be seen as rational.

In a case such as this, one would need to delve deeper and determine what (if any) aspects of potential psychopathology might be influencing him. For example, does he recognize the outcome he is hoping for is unlikely? In contrast, does he appear to have another motive (such as suicide)? Are his actions consistent with his prior ("baseline") behavior?

Assessing psychopathology

A vital part of the evaluation will be to determine if a mental illness is the primary driving force behind the decision to stop eating. In some cases this may not be difficult to determine, such as the case of a depressed prisoner who states that he deserves death for his crime, the delusional prisoner who reports that there are microchips in the food that will cause another to gain remote control of his bodily functions after ingestion, or the catatonic patient who is immobile and mute. In such cases, the motive or cause behind the food refusal would not be difficult to determine with a clinical interview or appropriate physical exam (e.g., a Bush–Francis screen for catatonia). Often cases are more complex, but sometimes initial "red flags" can help begin to guide the evaluator.

A study by O'Connor and Johnson-Sabine (1988) reviewed cases of hunger strikes in a female remand prison in London as well as Broadmoor Hospital and one additional case at a London Psychiatric Hospital. They determined that hunger strikes were highly correlated with mental illness, with 14 out of 25 (whose charts were available to review) being diagnosed with a mental illness. This study also pointed out that cases where a prisoner refused all oral fluids as well as food (i.e., "dry" hunger strikes) were correlated with psychosis. In a study of British inmates in Lincolnshire, England, from 1978 to 1986, mental illness was also highly prevalent among hunger strikers (Larkin 1991). Two aspects of behavior appeared to increase the likelihood of mental illness driving the decision to fast: (1) if they refused (or were unable) to state why they were fasting, or (2) if they refused all fluids as well as food (i.e., "dry" hunger strikes). The study reaffirms the importance of a thorough evaluation of the prisoner for psychopathology in either of these findings. A "dry" hunger striker will be at risk of death much sooner and may be seeking death, rather than only risking it for a cause (or be easily distinguished from a "reactionary" prisoner who will not put himself at risk). The prisoner who cannot state a reason for a hunger strike may not be able to manipulate information rationally in order to engage in rational decision making.

Despite the O'Connor and Larkin studies, food refusal and mental illness may not be as highly correlated as their results initially suggest. Both studies were retrospective, and either did not determine if the fasting prisoners with a history of mental illness lacked capacity at the time of their fasting (O'Connor and Johnson-Sabine 1988) or had limited information in this regard (Larkin 1991). In addition, in the O'Connor study only two of those diagnosed with a mental illness had expressed motives that were strongly suggestive of psychosis (i.e., food being poisoned and food causing brain damage), yet six of them had a psychotic disorder among their diagnoses. This suggests that the remaining four with a psychotic disorder may have had capacity at the time (suggesting that the diagnosis of a mental illness may not have been causative in the decision to fast). The Larkin study also included a personality disorder as qualifying one as having a mental illness, potentially making the association seem higher than it was. In a 1999 article by Dr. Beatrice Brockman, she noted that among the 15 evaluations she performed for assessing competence to engage in a hunger strike, she opined a lack of competence in only one (and the judge in that case disagreed). While her report was anecdotal, its value may lie in the fact that it was composed of cases that were all personally evaluated by a single psychiatrist (Brockman 1999).

As with competence in regard to refusing medications or medical intervention, each case must be considered within the context of its own unique set of clinical circumstances. For example, a prisoner with a diagnosis of schizophrenia may still possess competence to engage in a hunger strike. The challenge in instances such as these is to determine the degree to which the symptoms of mental illness affect the prisoner's motive for fasting. Or put another way, does the prisoner's motive for fasting flow from a mental illness, and, if so, to what extent? Situations in which comorbid mental illness is present along with a seemingly rational reason for a protest fast can be more complicated. For example, a depressed prisoner who states a protest over the conditions of his confinement may be using the pretense of a hunger strike in order to act upon suicidal intent.

The psychiatrist may encounter extremely complicated cases in which clarifying a prisoner's motives for a hunger strike becomes challenging. Consider a case in which the conditions of confinement appear to have caused the symptoms—such as prisoner abuse leading to posttraumatic stress disorder (PTSD) or depression. In such a situation the prisoner's baseline behavior will likely change and he will be symptomatic, express hopelessness, and may quite rationally conclude that a hunger strike is his only means of protest available. Dealing with suspected prisoner abuse is outside the scope of this chapter, but the issue brings up the importance of recognizing that the psychopathology present may be a factor in one prisoner's competence, while it could be the rational cause for a protest in another. In such a situation where prisoner abuse is suspected, it is the ethical duty of the psychiatrist (regardless of the role he or she is in) to report this to the higher authorities until such an allegation is adequately investigated (Knoll 2014). All steps toward the prisoner's safety, well-being, and dignity will be the most effective intervention in such cases (see also, Legal and Ethical Issues in Managing a Hunger Strike, below).

Additional considerations regarding the evaluation of hunger strikes

In addition to the above factors, it is important for the prisoner to demonstrate the knowledge that he will likely lose the ability to make decisions for himself, should the fast be prolonged. Such situations highlight the importance of the prisoner assigning a proxy decision maker or clearly delineating advanced directives (see below, the Management of the Competent Hunger Striker). Another challenging scenario may arise when a prisoner is undergoing a hunger strike as part of a group. On the surface, a group hunger strike may seem to be more likely to involve competent participants, due to the organization involved and because it would be unlikely that a mentally impaired leader would be followed by a group. However, there remains a risk that some peer coercion may be at play, which could impact a vulnerable prisoner. Should evidence of coercion come up during the evaluation, the psychiatrist has an obligation to determine an avenue for safely extricating the vulnerable prisoner from such coercive influences. This may involve moving the individual to another area of the prison.

In addition to assessing decision-making capacity, a psychiatrist may be asked to make recommendations for managing a prisoner who engages in a hunger strike. The potential recommendations will be guided by the opinion on competence itself—i.e., for recommending treatment (over objection if necessary) for those whose mental illness impairs their competence to engage in a hunger strike.

MANAGEMENT OF THE INCOMPETENT FASTING PRISONER

In the case of a fasting prisoner whose mental illness is driving the refusal of food, the management should be aimed at addressing the mental illness. Thus, an assessment of capacity should be done as early as possible, so that there is time to implement treatment strategies to avoid permanent damage from prolonged fasting. In some instances a prisoner's mental illness may cause him to pose a danger to himself, and a court order for treatment over objection may be needed. It is also notable that situations like these are often not as black and white as they seem, and often even a psychotic prisoner may consent to accept some forms of nutrition, which might buy enough time for him to respond to medications or other treatment.

MANAGEMENT OF THE COMPETENT HUNGER STRIKER

There are few studies examining the phenomenon of early mental status changes in hunger strikers. However, some data may be considered from the work of Anthropologist Daniel Fessler who studied fasting among eating-disordered patients. While he noted that some showed signs of abrupt early psychosis, many showed more subtle psychological changes in the face of starvation. One observation was that starvation caused patients to become more impulsive and obstinate, potentially due to a decrease in serotonergic activity (Fessler 2003). Although most of the early changes rarely appeared to affect competence, the results suggest a correlation with more cognitive flexibility earlier in the fasting process, and perhaps more hostility and rigidity later (i.e., a reasonable resolution or compromise to the hunger strike may be more likely to be reached early on, as opposed to later in the process).

In addition to the Fessler study, an earlier report from Israel noted that a pre-existing psychotic disorder (or personality disorder with a history of psychotic episodes), increased the risk of psychosis earlier on in the process of fasting (Robinson and Winnik 1973). Thus, a hunger striker with schizophrenia may be at higher risk for early psychosis, even if competent at the onset of the fast. Another important consideration to address involves the assignment of a substitute decision maker to serve in the instance that a prolonged fast causes a prisoner to lose his competence. On a long enough timeline, all hunger strikes will lead to incompetence, and it is important to ask the prisoner to assign someone to speak for him in those instances, or to set out a clear advance directive. Some hunger strikers may prophylactically consent to artificial feeding or intravenous nutrition in the instance that the fasting has led them to lose consciousness. In contrast, some may only consent to this if certain demands have been met. Regardless, the discussion of this issue should be made as early as possible to help ensure that those decisions are made when the prisoner is most lucid.

Should a hunger striker wish to end a fast but feel compelled to continue due to peer pressure from other prisoners (such as in a group hunger strike), he must have an avenue to express this to his treatment team without concern that it will get back to the other hunger strikers. His motives may range from simply avoiding the feeling of shame, to fear of retaliation. In these instances confidentiality must be assured, as well as an avenue to provide nourishment to the prisoner without concern for the others knowing he has decided to stop his fast. Medical management of hunger strikers will be largely performed by the internist on duty, and may involve convincing the prisoner to accept some supplementation to help prolong and delay permanent injury. Some prisoners will concurrently accept intravenous fluids and/or treatment for infection or pain. Some may accept nutritional supplements, and may benefit from vitamin B or other supplementation (Oguz and Miles 2005). Therefore, it is important to offer these, as they may delay or reduce the risk of permanent injury.

Regarding the management of a competent hunger striker, it is important to recognize that despite the fact that a hunger striker often leaves no doubt to his competence, the correctional institution will often be successful in obtaining

a court order authorizing force-feeding. Although a psychiatrist would not typically be involved in a force-feeding procedure, forensic psychiatrists are often consulted (both formally and informally) when ethical dilemmas arise among the treatment team.

LEGAL AND ETHICAL ISSUES IN MANAGING A HUNGER STRIKE

When a competent individual in free society engages in a prolonged hunger strike, it would be rare that a life-threatening situation would lead to the person being force-fed (especially if a clear advance directive was documented). However, in the United States, when a prisoner engages in a hunger strike, the situation becomes complicated due to his being in the custody of the state. In such cases, the courts must weigh the prisoner's rights against the interests of the state. The prisoner's rights are often argued in regard to personal liberty interests/autonomy, the first amendment right to free expression, and the right to refuse treatment (common law doctrine of informed consent and the right to privacy). The state's interests are often argued in regard to prevention of suicide, maintaining order, duty to provide medical care, and the overall prevention of death (Ohm 2006).

When weighing the two party's interests, it is notable that some early cases in the United States sided with the prisoner's right to continue food refusal. In the 1982 case of *Zant v. Prevatte*, the Georgia Supreme Court upheld a hunger striking prisoner's right to continue his fast, based on his right to privacy, which the Court found outweighed the state's interest in keeping a prisoner safe from harm (Ohm, 2006; 248 Ga. 832, 286 S.E.2d 715, 1982). However, more commonly courts will authorize force-feeding when a prolonged hunger striker is at risk of death, if not well before that point (Ohm 2006). Jurisdictions vary widely in regard to the correctional facility's authority to initiate force-feeding, some even authorizing this at the discretion of the treating physician without a court order. For example, an Illinois statute authorizes a treating physician to initiate force-feeding "to prevent death, damage, or impairment to bodily functions" (Ill. Comp. Stat. 5/3-6-2, 2004).

Although seemingly at odds with rational logic, one state interest that has been successfully cited to supersede the individual interests of the prisoner is that of force-feeding the prisoner to prevent a "security" risk based on interference with the orderly administration of the prison. A group hunger strike may potentially put some security interests at risk, it is difficult to argue that one hunger striker puts anyone at risk of harm but himself. Nevertheless, courts often give broad latitude and deference to correctional administrator's concern over security risks. For example the Supreme Court of Connecticut in *Commissioner of Corrections v. William B. Coleman* (2012) affirmed a lower court's granting of a permanent injunction authorizing the force-feeding of a hunger striking inmate. The court stated its opinion in part noting that allowing the hunger strike to continue would present "an unacceptable risk to the safety, security and orderly administration of the prison system." A competent hunger striker is not seeking to end his life, but the state interest in preventing "suicide" is often also successfully cited in cases ruling in favor of correctional facilities. For example, the Washington State Supreme Court referenced, in part, the prevention of suicide as the justification for authorizing for a hunger striking inmate (*McNabb v. Dept. of Corrections* 2008).

Therefore, it is not uncommon that the correctional facility will be successful in requesting court authorization for force-feeding. Such situations often leave medical staff in uncomfortable situations. While a court may grant the legal authority for a correctional institution to force-feed a prisoner, such a practice may be regarded as unethical in many, if not all, circumstances (WMA, 2006; Arnold, 2008, Rubenstein and Annas 2009). While ethical practice is often supported with legal authority, the latter does not invariably ensure the former.

ETHICAL GUIDANCE

When attempting to determine guidance for the proper ethical course in managing hunger strikes among the incarcerated, the most authoritative guidelines have been developed by the WMA in its Declaration of Malta on Hunger Strikers in 1991, and later revised in 2006. The Declaration focuses on detained individuals (such as immigration detainees in addition to prisoners) and contains 7 ethical principles and 13 guidelines consistent with those principles. Among the guidelines are ways in which to approach the difficult—and usually rare—incident where a hunger striker has reached the point where he is at risk of death and has left clear directives against artificial feeding or other hydration:

> Physicians may consider it justifiable to go against advance instructions refusing treatment because, for example, the refusal is thought to have been made under duress. If, after resuscitation and having regained their mental faculties, hunger strikers continue to reiterate their intention to fast, that decision should be respected. It is ethical to allow a determined hunger striker to die in dignity rather than submit that person to repeated interventions against his or her will. (Guideline 11, WMA, 2006)

Other exceptions include the question of whether or not the purpose of the hunger strike has been addressed partially. For example, consider this case: if a person loses capacity during a hunger strike before he is informed that some, but not all, of his demands have been met. The Malta guidelines therefore provide steps to ensure that all other avenues have been explored prior to any physician making the ultimate decision to defer intervention.

It is also important that one not only focuses on the decision-making capacity assessment but also be receptive to a potentially larger picture emerging in some cases. For example, among hunger strikers at the detention facility at Guantanamo Bay, Cuba (GTMO), there has been evidence that prisoner abuse was a factor in their protest (testimony of Dr. Steve Miles, *Dhiab v. Obama* [transcript]; The Constitution Project 2013). A full analysis of this topic is outside the scope of this chapter, but it has been well documented that many GTMO prisoners gave credible statements about being tortured while in custody and experienced undiagnosed and untreated PTSD and depression (Clark 2006; The Constitution Project 2013). This demonstrates a potential situation where one is severely depressed, desperate, and hopeless, and may yet express a valid protest about mistreatment. Thus, it is important to be mindful that the stated purpose of a hunger striker may be legitimate, despite the presence of significant symptomatology.

OTHER POTENTIAL ROLES

A forensic psychiatrist may also contribute to the treatment team as a liaison to the medical staff to advise on approaches that may help a prisoner remain in optimal health, while allowing him to "save face" in the instance that the person may be expressing ambivalence about continuing the strike. On the one hand, there is the ethical duty of a treating physician to offer the prisoner whatever means will help him return to accepting adequate nutrition of some kind. On the other hand, unethical or coercive strategies should be avoided. And amid all of this, the psychiatrist and medical staff should remain mindful of their own personal biases, and countertransference. Although not immune from these issues, this suggests another area in which a psychiatrist can contribute, such as in promoting more positive team dynamics.

SUMMARY

Hunger strikes in correctional settings have the potential to become intensely dramatic episodes for both the correctional staff and the prisoner. Something seemingly as simple as knowing when and when not to apply the term "hunger strike," can be significantly important in these situations and can help guide the clinician toward a proper and effective management strategy. The psychiatrist can assist in many ways, including forming an opinion on a hunger striker's competence, assisting in the management of incompetent as well as competent prisoners who refuse food, and providing education to the treatment team.

Important aspects of the assessment and management of food refusal in prisoners include:

- Early examination for competency
- Determining the stated reason and ruling out motives driven by mental illness
- Avoiding or minimizing an adversarial situation with the inmate
- Application of the WMA Declaration of Malta for ethical guidance

Antisocial personality disorder and psychopathy

ANTHONY MADEN AND WILLIAM NEWMAN

INTRODUCTION

Antisocial personality disorder (ASPD) is the term in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (*DSM-5*). The preferred term in the *International Classification of Diseases*, 10th revision (*ICD-10*) is dissocial personality disorder. The main distinction is that ASPD requires a history of childhood conduct disorder. For most purposes, the terms can be considered synonymous, and ASPD will be used throughout this chapter. Antisocial personality disorder is fairly common, with a community prevalence of 2%–3% and a massive 60% among male prisoners (Moran 1999). The implication of the latter figure is that ASPD is statistically the norm in many correctional facilities and for individuals working with offenders.

Except where otherwise indicated, the term *psychopathy* denotes the condition as operationally defined by Hare and as measured by the *Psychopathy Checklist, Revised* (Hare 2003). The prevalence of psychopathy has been measured at about 0.6% in the general population (Coid et al. 2009). The prevalence of psychopathy in prison populations is in the range of 15%–20% (Hare 1991).

Of the personality disorders, psychopathy is most commonly linked to individuals meeting criteria for antisocial and narcissistic personality disorders (Blackburn et al. 2003). Though many conceptualize psychopathy as a severe subset of ASPD, that is an oversimplification. Many individuals meet criteria for ASPD without meeting criteria for psychopathy. Another group meet criteria for psychopathy without meeting criteria for ASPD. Babiak and Hare (2007) describe individuals they termed "snakes in suits," the psychopath who integrates into the workforce and can wreak havoc, often without developing a criminal record.

BRIEF HISTORY OF ASPD AND PSYCHOPATHY

The historical origins of ASPD and psychopathy are typically traced back to Prichard's (1835) concept of moral insanity, which he defined as a disorder of the "feelings temper and habits" in the absence of cognitive impairment, delusions, or hallucinations, such that the individual is "incapable of conducting himself with decency and propriety in the business of life" (p. 15). When Prichard wrote in 1837, his patients would have included many with organic conditions who would not today be regarded as having ASPD or psychopathy. However, his notion of a man lacking the usual signs and symptoms of mental illness but nevertheless being incapable of following normal social conventions is remarkably close to modern ideas of ASPD and psychopathy.

Whatever the term has been used to describe it over the years, the concept of psychopathy has inescapable moral overtones. The uneasy interface between medicine and morality was recognized by Maudsley in 1874 when he observed that moral insanity "has so much the look of vice or crime that many people regard it as an unfounded medical intervention." In other words, it is difficult or impossible to distinguish criminality from psychopathy.

Moral insanity was widely accepted by U.S. and European Courts of Law throughout the latter part of the nineteenth century. It was later supplanted by the concept of psychopathic inferiority, coined by Koch (1891), who attributed the problem to "a congenital or acquired inferiority of brain constitution." Despite the archaic terminology, Koch deserves a mention because he argued against punishment in favor of special institutions for such individuals, an argument that remains pertinent over 100 years later and was actually implemented by the United Kingdom in its Dangerous and Severe Personality Disorder (DSPD) program, discussed later in this chapter.

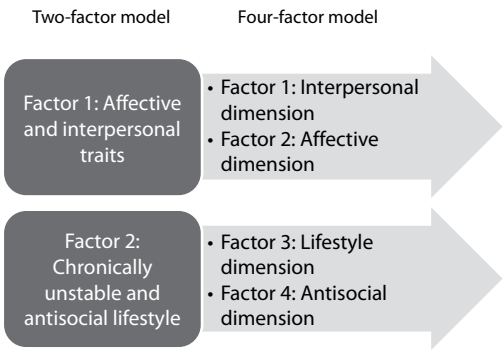
Henderson (1939) was influential in shaping the modern concept of ASPD by defining individuals who "throughout their lives exhibit disorders of conduct of an antisocial or asocial nature." At around the same time, Cleckley (1941) established the concept of a psychopathic personality with core criteria relating to antisocial behavior. Cleckley was particularly influential because of his emphasis on the

fact that ASPD was not found only in criminals. Cleckley showed that, although there may be a massive overlap between ASPD and offending, the association is not absolute. Cleckley's views were particularly influential on *DSM* and *ICD* classifications of personality disorder. They also influenced Hare (1991) in his development of an operationally defined concept of psychopathy.

We continue to struggle with these issues because they are insoluble. Morality and science are different, but equally valid, ways of approaching the same problem. The funding of scientific research in the field is to a large extent driven by the social and moral ramifications of a condition that is associated with violence and other offending behavior. The World Health Organization (Krug et al. 2002) rightly describes violence as "a universal scourge that tears at the fabric of communities." ASPD and psychopathy are the mental disorders most strongly associated with violent offending. These disorders are of scientific interest partly because of their moral connotations and unfortunate legal outcomes.

MEASUREMENT AND THE PSYCHOPATHY CHECKLIST

Hare refined and operationalized Cleckley's notions of a psychopathic personality to construct the 20-item Psychopathy Checklist (Hare 1991, Hare 2003). Each item is scored between 0 and 2, giving a range of total scores of 0–40. A score of 30 and above (often modified to 25 and above outside the United States) is the most commonly used cut-off to establish psychopathy. Hare has presented a two-factor and four-factor model over the years to characterize the items on the Hare Psychopathy Check List-Revised (PCL-R) (Harpur et al. 1989; Neumann et al. 2007). The four-factor model was essentially derived from the two-factor model (Figure 59.1).



Two-factor model
Four-factor model
Factor 1: Affective and interpersonal traits
• Factor 1: Interpersonal dimension
• Factor 2: Affective dimension
Factor 2: Chronically unstable and antisocial lifestyle
• Factor 3: Lifestyle dimension
• Factor 4: Antisocial dimension

Figure 59.1 Transition from Hare's two-factor model to four-factor model of psychopathy.

Hare's work represented a major advance in the field because, for the first time, it was possible to reliably measure the degree or severity of psychopathy—and, by extension, some forms of ASPD. Before the advent of the PCL-R, the concept of psychopathy had become discredited because of the looseness of the definition and its pejorative overtones. The advent of a reliable, standardized measure rescued psychopathy from becoming no more than a lay term of abuse and rehabilitated it as a scientific concept.

At this point, psychiatric diagnoses are defined mainly by their symptoms. The problem in the case of psychopathy is that a large part of the symptomatology consists of aggressive and irresponsible behavior. The PCL-R has not solved this problem, but it has at least allowed us to measure and assess the symptoms more reliably. The first step in any process of scientific understanding is that of measurement.

The other major advance represented by the PCL-R was its recognition that, in individuals with ASPD, self-report will often be unreliable. Until the PCL-R came along, most standardized assessments of personality or personality disorder had relied on self-report. Hare argued that self-report was particularly unreliable in the case of an individual with psychopathy, so the PCL-R relies on the use of historical records as well as direct observations at interview.

The PCL-R has been extensively validated against various measures, and there are now norms for the general population as well as for offender and mental health populations. Table 59.1 lists some of the pertinent studies that have assessed the predictive utility of the PCL-R. Hare's website (http://www.hare.org) frequently updates a list of published studies pertinent to the PCL-R.

Table 59.1 Sample of pertinent studies that have established predictive utility of the PCL-R

Author(s)	Year	Publication	Brief summary
Hemphill et al.	1998	*Legal and Criminological Psychology*	Reported on utility of PCL-R compared to other predictive factors
Hare et al.	2000	*Behavioral Sciences and the Law*	Compared international samples to North American samples, where most of the early studies occurred
Skeem and Mulvey	2001	*Journal of Consulting and Clinical Psychology*	Removed nonspecific antisocial behaviors from analyses relating psychopathy and violence
Tengstrom et al.	2004	*Criminal Justice and Behavior*	PCL-R maintained predictive utility after controlling for variables
Weizmann-Henelius et al.	2015	*The Journal of Forensic Psychiatry and Psychology*	Assessed predictive validity of PCL-R for violent recidivism in female offenders

RECENT DEVELOPMENTS IN THE TREATMENT OF ASPD AND PSYCHOPATHY

The fundamental problem is that the concepts of psychopathy and ASPD apply to people who break the rules despite being fully aware of them. As a result, such people are often subject to censure or punishment. Mental health personnel have often held attitudes toward ASPD that are ambivalent at best and sometimes frankly hostile. It came to be known as a diagnosis of exclusion, at times reserved for patients considered unlikable for staff. In recognition of this phenomenon, the U.K. government developed a document titled: "Personality disorder: No longer a diagnosis of exclusion," as a sign of its determination to remedy the problem (Snowden and Kane 2003).

The origins of the negative attitudes toward the diagnosis of ASPD can be seen in the history of the concept, which from the beginning has had moral connotations. The diagnostic label can be viewed by some as an attempt to justify antisocial or aggressive behavior and provide offenders with a built-in excuse or mitigation. As noted above, that dilemma is not new and in some ways minimally changed since Maudsley's 1874 comment about the impossibility of distinguishing this particular medical diagnosis from bad behavior.

The challenge to clinicians is to develop pragmatic ways of negotiating these dilemmas. Mental health services often argue that individuals with ASPD would be better placed in correctional institutions, while the latter may expect psychiatry to relieve them of the burden of dealing with the most seriously personality disordered individuals. One of the issues to be addressed in treatment of personality disorder is how to judge the outcome. Some critics are dismissive of offending rates as a measure of success because many core features of the personality disorder may remain unchanged. This chapter considers an attempt in the United Kingdom to expand the role of mental health services in dealing with severe ASPD as an example of attempting to develop a system to address this issue.

OFFENDING BEHAVIOR PROGRAMS

Prisons and other correctional services can be characterized historically as swinging between the extremes of the rehabilitative ideal on one hand and therapeutic nihilism on the other. There is a tendency either to have unrealistic expectations of the extent to which offenders can be reformed, or to be unduly pessimistic and to reduce prisons to the function of locking up and counting their inmates.

The application of cognitive behavioral principles to the development of offending behavior programs (OBPs) represents one way forward. OBPs can be incorporated into an ordinary prison or probation regime, although most commentators suggest OBPs are more likely to be successful if the regime also fosters prosocial behaviors. There is now a vast literature on OBPs, which falls outside the scope of this chapter. McGuire (1995) serves as a good introduction to the field. Craig et al. (2013) is more up to date and includes a paper by McGuire on developments in the area since his original contribution.

OBPs are not framed in medical terms, so interventions primarily occur in response to types of repeated offending. Most of the program participants would probably meet criteria for ASPD (and possibly psychopathy), though the target of treatment remains offending behavior rather than personality.

Overall, the results from OBPs are encouraging, with significant reductions in recidivism rates. OBPs have proliferated because of their results and the fact that they are heavily manualized. Staff can be trained to deliver them in a fairly short time, and they can often be delivered partly or wholly to groups. All this increases efficiency in an area where the large number of potential candidates and tight budgetary constraints make cost a major issue.

There are several potential issues when enrolling individuals with ASPD and psychopathy in OBPs. The first problem is that because OBPs do not usually incorporate a diagnostic framework, it can be difficult to generalize findings. The encouraging figures for overall success rates may not apply to those with more severe personality disorders. A persistent question by some authors has been the extent to which such programs are effective in individuals with psychopathy (Wong et al. 2006).

In fact, we know that the higher the psychopathy score, the less likely it is that OBPs will succeed in reducing re-offending rates. Some colleagues have even suggested that treatment may increase re-offending rates in those with high PCL-R scores. That has not been confirmed, but these individuals are more likely to drop out of treatment, to subvert a program, or to fail to respond. As Wong and Hare (2005) noted, the wrong treatment is likely to make psychopaths worse.

Attempts to identify the right treatment have so far attempted to adapt the CBT principles of OBPs while making the delivery more intensive and safeguarding against attempts to subvert, divert, or otherwise undermine it. A good example is the U.K. Prison Service's Chromis Programme for high-risk offenders with high levels of psychopathy (Tew and Atkinson 2013). Motivation is also a central issue, with general agreement that any progress is likely to require collaboration. The principle of enlightened self-interest has been put forward as a way of encouraging narcissistic and self-centred individuals who may be encouraged to become more prosocial. The problem is that the principle only comes into play at a fairly late stage, when offenders have begun to suffer serious punishments in response to serious offending. In public health terms, there is a sense about such programs that they may offer too little, too late, and at too great a cost.

THE DUTCH TBS SYSTEM

The Dutch TBS system has a history of looking after violent and sexual offenders since 1928 (de Boer and Gerrits 2007). TBS is an acronym for a Dutch term that translates as "at the disposal of the government," which summarizes

the position in which the offender–patients find themselves. The system is based on a legal provision that allows a court to order that certain categories of convicted offenders will serve the prison term warranted by their offence, before going on to a TBS institution for a mandated program of treatment. Detention within the TBS facility is indefinite, subject to regular review by a tribunal. The later stages of compulsory treatment and supervision will be in less secure facilities and eventually in the community, if and when suitable progress is made.

The TBS system seemingly overcomes the difficulties created by ASPD being used as an excuse for criminality because it allows the court first to deliver punishment before mandating treatment. Critics would argue that the additional period of detention in the TBS service amounts to further punishment, but the system is widely accepted in the Netherlands. In fact, most criticism is centered on the possibility that offenders may move through the system too quickly, rather than that their civil liberties are infringed upon. The ethical questions considered with the TBS system are similar to those considered with sexually violent predator (SVP) laws in the United States (Sreenivasan et al. 2010).

As with OBPs, the TBS system is based on offending and risk rather than diagnosis. Holland has no life sentence and TBS is part of the alternative. In practice, the TBS system treats offenders with a range of diagnoses, but many have ASPD or psychopathy. It uses a range of treatments, mostly delivered by psychologists or specially trained therapists. CBT has become the predominant psychological treatment in recent years. In addition, there is a strong vocational element, with workshops and other employment facilities of a comparable standard to those in the outside world. These vocational aspects are considered to be of at least equal importance, alongside psychotherapy, and they generally take up more of the patient's week. Medical input is largely restricted to prescribing antilibidinal or other medications, the latter including antidepressants and antipsychotics for the mentally ill.

The TBS system was not developed with a particular diagnosis in mind, but it highlights themes that emerge whenever services attempt to treat ASPD and psychopathy. First, it is a long-term endeavor; after 6 years' detention, 20% of patients are deemed unlikely ever to be discharged to the community. Second, the goal is safe management in the community rather than cure; those who are discharged remain subject to long-term, mandatory supervision. It may be that the service's successes owe as much, if not more, to prolonged supervision as to any intervention within the institution. Third, the treatment of comorbid disorders such as depression, substance misuse, and paraphilia is central to risk reduction.

U.K.'S DANGEROUS AND SEVERE PERSONALITY DISORDER (DSPD) INITIATIVE

The origins of the U.K.'s DSPD system reflect a major problem arising from a strict, dichotomous approach to punishment versus treatment as a response to offending by those with ASPD and psychopathy. The problem was that an approach that focused on punishment did not adequately address issues of continuing risk. The DSPD service grew out of a concern that mentally disordered offenders with severe ASPD or psychopathy were being released at the end of lengthy sentences with their problems unaddressed and their risks unchanged.

After a series of high-profile cases of re-offending in these circumstances (mainly a series of killings by predatory pedophiles who also met criteria for psychopathy) (Oliver and Smith 1993), the United Kingdom in 1999 allocated a substantial sum of money to setting up 300 high-secure beds for the treatment of men with a dangerous and severe personality disorder. The planning of the service was influenced by Hare's concept of psychopathy and used a PCL-R score as a guideline for admission, making DSPD similar to psychopathy. In effect, the program was an experiment in the treatment or management of psychopathy.

The most controversial aspect of the service was that half of the 300 beds were to be in highly secure hospitals, where patients would be detained for treatment under the U.K.'s Mental Health Act. The overwhelming weight of psychiatric advice was against the idea, which amounted to a heavy-handed attempt to legislate an instant solution to dilemmas about the management of psychopathy that had troubled clinicians for nearly 200 years.

The other essential ingredient of the government's strategy involved providing considerable resources. Each hospital bed cost around $600,000 per year and the minimum stay was predicted to be at least 2 years. With hindsight, it is apparent that the service was able to develop only because it came at the time of the credit-fueled bubble that preceded the 2008 financial crisis.

Treatment in psychiatric hospitals was particularly problematic. One of the major clinical issues is that hospitals operate according to a medical model that often involves taking away responsibility from a patient, particularly during the more severe phases of an illness. This removal of responsibility is recognized as problematic in all areas of psychiatry, hence the attempt to emphasize rehabilitation or recovery in patients with psychotic illnesses. The medical model is even more problematic in ASPD, where one of the basic problems is that the individual fails to accept responsibility for his actions. The problem is made worse by a system that further encourages the individual to give up responsibility. Patients within the hospitals rapidly develop the expectation that it was the hospital's job to make them better, rather than something they could achieve in collaboration.

The other problem involved deciding what treatment should be administered. The choice was cognitive behavioral therapy, similar to the OBPs. The reasons included a good evidence base for ethicacy; a tight, well-defined structure to the treatment that minimized problems when dealing with psychopathic individuals; and the fact that the treatments can be delivered (relatively) efficiently. The potential cost

savings were negated by the massive costs of a highly secure bed.

At the beginning, there was a general concern about whether individuals with psychopathy could or would benefit from treatment. As in other attempts to treat high-risk individuals, these concerns were addressed by making the treatment intensive, giving a lot of emphasis to program integrity and staff supervision, and choosing the correct, tailored intervention. It was recognized, for example, that there is no point in teaching skills to those individuals who have no deficits in that area and would be likely to use any new skill in a manipulative and antisocial way.

In fact, a bigger problem proved to be the delivery of treatment rather than its content. An evaluation of the service showed that a relatively small amount of the time spent in an expensive institution involved meaningful therapeutic work. Burns et al. (2011) found that actual levels of treatment delivery were far below what was intended, whether because of the difficulties of working with these particular individuals, the difficulties of working in institutions not used to providing intensive psychological treatment, or both.

The service for DSPD opened in 2004 and closed soon thereafter, in 2010. Howells et al. (2007) described some of the challenges the program faced. Tyrer et al. (2009a,b) focused on the difficulties of selecting a tiny number of patients from a large pool of potential candidates. The DSPD program commissioned several evaluations of outcomes, with disappointing results. At best, the DSPD program was an expensive way of achieving a small amount of psychological change in a small proportion of the patients admitted to the service—who themselves composed only a small proportion of high-risk offenders.

The DSPD service was expensive because it involved a long stay in either a hospital or a high-security prison. It illustrates one of the dilemmas in treating ASPD and psychopathy. ASPD is common in offender populations. Correctional systems must therefore decide whether to devote resources to the intensive treatment of a small number of very high-risk individuals, or to give a less-intense treatment to a much greater number, including many who pose lower levels of risk.

As a general principle, there is much greater potential for achieving the benefit of risk reduction if one begins with higher-risk individuals. But even assuming the intended reductions can be achieved, the highest-risk individuals may not be able to make much progress through the system, largely because of the offences they have already committed. Deciding how to approach this problem remains a dilemma.

Closing the DSPD program was followed by a new emphasis on psychological treatment within the U.K.'s prisons, much more along the lines of conventional OBPs. The aim was to develop psychologically informed planned environments (PIPEs). They are specifically designed prison environments where staff members have additional training to develop an increased psychological understanding of their work. The units have activities with the potential to maintain gains made in other interventions, i.e., to support OBPs. The main aim is to get around the problem that confronts many treatment programs in prison. After leaving the therapy room, the individual has to return to an ordinary prison environment where attitudes and behavior are often the opposite of the prosocial standards taught during treatment. OBPs work partly by reducing the factors that lead to antisocial attitudes and behavior, but also by encouraging and facilitating prosocial behavior. Each arm of the treatment depends on the other.

TREATMENT OF ASPD AND PSYCHOPATHY

The DSPD project is largely considered a failure in terms of its stated objective of providing public protection by improving the treatment of dangerous offenders with severe personality disorders. It did, however, have a number of incidental benefits, one of which was to raise the general profile of personality disorder and personality disorder services in the United Kingdom. In turn, it led the National Institute for Clinical Excellence (NICE) to publish guidelines on the treatment, management, and prevention of antisocial personality disorder. NICE is a government body that produces guidance for clinicians in all fields of medicine. Just a few years earlier, it would have been unthinkable for NICE to produce a medical guideline in the field of ASPD.

The NICE guideline is divided into six sections, with one devoted to the treatment of ASPD and comorbidity and one devoted to psychopathy and severe personality disorders. The other four sections concern general principles in approaching ASPD: prevention; assessment and risk management; and the organization and planning of services. It reflects the state of our knowledge that a treatment guideline should have so much emphasis on aspects other than treatment. Unfortunately, there remains little to say about how to effectively "treat" the core features of ASPD and psychopathy.

As a result, the section on treatment emphasizes mainly the treatment of comorbid disorders such as drug and alcohol misuse or other psychiatric disorders such as depression. It is acknowledged that treatment of the core syndrome is problematic and may not be possible, but the overall situation, not to mention the associated risks, may be greatly improved by treating comorbid problems. Hence, despite the underlying pessimism about changing the personality disorder itself, there is some encouragement of an optimistic and positive attitude toward treatment. The rationale is that by successfully treating problems such as drug or alcohol misuse, the quality of life and risk of offending may be dramatically reduced. The point is often made that even more serious offenders spend most of their waking hours in activities other than offending. One aim of treatment is to increase the proportion of time spent not offending, and that can be achieved without actually treating the underlying personality deficits.

Current treatment recommendations in the literature for addressing ASPD and psychopathy are largely in line with the NICE guidelines described above. The greater the degree of psychopathy, the more difficult it is to deliver treatment and the lower the chances of success. There is no easy way around this problem, and most attempts focus on delivering intensive treatment; increasing motivation and compliance; and preventing subversion or drift in treatment. Once comorbid disorders have been addressed, management of the underlying personality disorder is often a long-term task in which the outcome is likely to depend as much on support and supervision in the community as on any specific intervention. The nature of the latter task has been nicely encapsulated by Tyrer and Bajaj (2005) in nidotherapy; it is acknowledged that the core aspects of the personality disorder will persist, and the task of the clinicians is to create an environment in which it is contained or cocooned so as to maximize quality of life and minimize risks to others.

Prediction is always difficult, but it seems unlikely that there will be any dramatic breakthrough in the social or psychological management of ASPD or psychopathy in the near future. The most likely scenario is that we will see greater refinement and extension of CBT techniques. So far, there is no sign of any pharmacological breakthrough either, except insofar as medication assists with comorbid disorders or provides symptomatic assistance in managing traits such as irritability and paranoia. It is not surprising, therefore, that when we look at future directions for research, the main focus is on the underlying organic abnormalities and early intervention.

RESEARCH INTO PSYCHOPATHY AND ASPD

A major problem is that psychopathy almost certainly encompasses a range of underlying conditions rather than a single entity. Studies of the brain have already found structural and functional correlates for impulsivity as well as for cold, calculating behavior.

A second issue is that much of the research in this area has been conceptualized not in diagnostic terms, but with reference to antisocial behavior or offending. The subjects may or may not meet the criteria for psychopathy, and it is not a straightforward matter to integrate the findings. When looking at the origins of antisocial behavior in childhood, the term *psychopathy* is avoided as a matter of principle, although studies are beginning to identify the importance of early deficits in empathy (Rowe et al. 2010; Blair et al. 2014).

In addition to the development of the PCL-R, there was an expansion of high-quality longitudinal studies, an early example being the Cambridge Study in Delinquent Development, the results of which are summarized in Farrington (1995). These cohort studies represent a massive commitment of time and resources, but they have gotten around the sampling problems that limited the usefulness of cross-sectional research. Some of the findings are stunning, such as a statistically significant continuity between behavior at the age of 3 and adult criminality (Stevenson and Goodman 2001).

DEVELOPMENTAL STUDIES

There is impressive continuity of antisocial behavior throughout the life span, yet at the same time the prevalence of offending changes dramatically with age. In the Cambridge study, three-quarters of juvenile offenders were convicted again between the ages of 17 and 24; and half were reconvicted between the ages of 25 and 32. At the same time, there was a dramatic decrease in offending after the peak age of 17. By the age of 32, a mere 6% of the Cambridge study's sample accounted for 50% of all the offending. Robbins (1966) found much the same in the United States.

The paradox was resolved by Moffitt (1993), who used the longitudinal Dunedin study to identify adolescence-limited and lifetime-persistent antisocial behavior. The latter group accounts for 5%–10% of the male juvenile offender population. They are more likely to have neurological problems. A detailed account of these studies falls outside the scope of this chapter, but there is bound to be considerable overlap between lifetime persistent offenders and adults with high psychopathy scores. Future research is likely to lead to greater integration between these areas.

PSYCHOPATHY AND THE NERVOUS SYSTEM

Much of the research on psychopathy and the nervous system has focused on demonstrating that parts of the brain are either under- or overfunctioning in psychopaths, or are under- or overdeveloped compared to the rest of the population. Raine's review (2013) makes it clear that the observed differences are many and varied.

For example, Raine et al. (1997) found evidence of reduced prefrontal function in murderers compared to controls. Soderstrom et al. (2000) found reduced blood flow in the hippocampal region in violent offenders with elevated psychopathy scores. Muller et al. (2003) reported similar findings. Reduced functioning in another brain region, the posterior cingulate gyrus, has been found in adult criminal psychopaths (Kiehl et al. 2001). Other brain regions with abnormal functioning include the superior temporal gyrus (Kiehl et al. 2004) and the amygdala (Glenn et al. 2009). A good case is made for structural and functional correlates of traits such as irritability, impulsivity, and aggression, although lacking any neat one-to-one correspondence.

The complexities in this area are perhaps best illustrated by Raine's (2013) discussion of the fact that his own brain scan resembles that of a serial killer, albeit a well-organized

and careful man who planned his killings meticulously. Both show good frontal lobe function, consistent with planning and organizational abilities. Raine concludes that normal people may have abnormal scans, and that the killer may be the exception that proves the rule. Certainly, one message is that there are no simple answers, and perhaps none would have been expected given the complexity of the issues under consideration. It may also be, however, that the information available to us so far misses the point. Two people have similar brain scans because they are both methodical planners, but that does not explain why one devotes his talents to an academic career while the other becomes a sadistic, serial sexual killer.

The differences between psychopaths and others are not limited to the esoteric field of brain abnormalities. A consistent finding is that low resting heart rate correlates with antisocial behavior in children and adults. Prospective longitudinal studies have also shown that low heart rate in childhood is a reliable predictor of later delinquent, criminal, and violent behavior. Farrington (1997) reported that of 48 potential early predictors of later convictions for violence, only two were reliable predictors independently of all other risk factors: low resting heart rate and poor concentration. The relationship has been so reliably identified that it has even been proposed that low heart rate could be considered as a biomarker for the diagnosis of conduct disorder in children and adolescents (Moffitt et al. 2008).

The most plausible explanation is that the low heart rate is a proxy measure for a low level of autonomic arousal, leading to increased sensation-seeking behavior. Alternatively, the low heart rate may represent relative fearlessness, and it has also demonstrated that children with low heart rates are less empathic than those with high ones. In related work, Gao et al. (2010) demonstrated that early impairment in autonomic fear conditioning predicts adult criminality.

SUMMARY

This chapter presents a glimpse of the empirical work on the developmental and neurological correlates of antisocial behavior, ASPD, and psychopathy. Many of the findings are correlational rather than causal, and it is important to keep a sense of perspective. Nevertheless, it is interesting to juxtapose this work with that on treatment. The lack of progress in treatment of the more severe forms of ASPD contrasts starkly with the rapidity with which organic correlates are being identified. Perhaps this is no coincidence and the reason for the difficulty of treating psychopathy and severe ASPD is that it is so firmly embedded in developmental and other abnormalities of the nervous system.

SUMMARY KEY POINTS

- Hare's development of the PCL-R allowed an individual's degree of psychopathy to be reliably measured.
- Although we have learned a lot about psychopathy since the concept was first introduced, the mental health system still has few answers about beneficial treatment options.
- The National Institute for Clinical Excellence (NICE) published useful guidelines to help with the management of ASPD and psychopathy.
- Much of the ongoing research on psychopathy focuses on developmental factors and potential early interventions during childhood.

Clinical assessment of aggression and violence

CHARLES L. SCOTT AND PHILLIP J. RESNICK

INTRODUCTION

The majority of those with mental illness are not violent. However, individuals with mental illness are at an increased risk for aggression compared to the general population (Swanson et al. 1990). With understandable concerns about the potential relationship of mental illness to violence, clinicians are increasingly asked to evaluate a person's risk of future dangerousness in various situations. These situations may include involuntary commitments, emergency psychiatric evaluations, seclusion and restraint release decisions, inpatient care discharges, probation/parole decisions, death penalty evaluations, domestic violence interventions, and fitness-for-duty evaluations.

Unfortunately, no interview or psychological test can predict future violence with high accuracy. Relatively infrequent events (e.g., homicide) are more difficult to predict than more common events (e.g., domestic violence) because they have a low base rate of occurrence. Despite this caveat, evaluators are generally expected to understand established factors and situations that are likely to increase a person's risk of future violence. This chapter summarizes important components of a structured clinical risk assessment to assist clinicians and forensic evaluators in the seemingly daunting task of evaluating future dangerousness.

DANGEROUSNESS AND DEMOGRAPHIC FACTORS

Dangerousness components

When conducting a violence risk assessment, the clinician may find it helpful to divide the concept of dangerousness into five components. The first component is the magnitude of threatened potential harm. Behavior may involve physical harm to persons or property, as well as psychological harm to others. In addition to identifying the likely target of violence, the degree of anticipated harm should be understood. For example, threatening to shoot someone in the face foreshadows a much greater risk of harm than threatening to kick someone on the leg.

The second component of dangerousness is the likelihood that a violent act will take place. Here it is important to clarify the seriousness of the person's intent to cause harm. A person's past history of acting on violent thoughts is the best predictor that violent intentions will be carried out. The third component is the imminence of the harm. For example, is the person threatening harm in the next 5 hours or the next 5 days? The fourth component examines the frequency of a behavior. Frequency is defined as the number of times a particular act has occurred over a specified period of time. The greater the frequency of an aggressive act, the higher the risk that the behavior will reoccur in the future. Situational factors constitute the fifth component of dangerousness. Situational factors that increase the risk of future violence include association with a criminally offending peer group, lack of financial resources and housing, easy access to weapons, or exposure to alcohol or illicit drugs (Scott et al. 2014).

Demographic factors

Demographic factors should be considered when assessing violence risk. First, data from the Epidemiologic Catchment Area study showed violent behavior was generally associated with younger age groups (Swanson et al. 1990). Second, males perpetrate violent acts approximately 10 times more often than females (Tardiff and Sweillam 1980). However, among people with severe mental disorders, men and women do not significantly differ in their base rates of violent behavior. In fact, rates are remarkably similar, and in some cases slightly higher for women (Lidz et al. 1993; Newhill et al. 1995). The MacArthur Foundation's Violence Risk Assessment Study monitored male and female psychiatric inpatients (aged 18–40) released in the community with mental disorders for acts of violence toward others

(Monahan et al. 2001). During the 1-year follow-up, men were "somewhat more likely" than women to be violent, but the difference was not large. Women were more likely than men to direct their aggression toward family members in the home environment. Violent acts by men were more likely to result in an arrest or need for medical treatment (Monahan et al. 2001). Finally, a person's socioeconomic status is relevant for assessing future dangerousness, as violence is nearly three times as common among individuals in lower income brackets (Borum et al. 1996).

Evaluating past violence history

A history of violence is the best predictor of future violent behavior (Klassen and O'Connor 1988). The evaluator can ask the individual to describe the most aggressive act they have ever committed, whether or not this resulted in a criminal arrest or conviction. Criminal and court records are particularly useful in evaluating the person's past history of violence and illegal behavior. For example, the age at first arrest for a serious offense is highly correlated with persistence of criminal offending (Borum et al. 1996). Each prior episode of violence increases the risk of a future violent act (Borum et al. 1996).

Prior criminal offending also increases the risk of future offending in individuals with mental illness. For example, in their study of over 15,000 people diagnosed with bipolar disorder, Webb et al. (2014) found that a history of criminal offending prior to a person being diagnosed with bipolar disorder was a strong independent predictor of criminality after the diagnosis was made.

Additional sources of information relevant in assessing a person's potential for violence include a military and work history. For those individuals who have served in the military, the clinician should review any history of fights, absences without leave (AWOL), disciplinary measures (Article XV in the Uniform Code of Military Justice), as well as the type of discharge. An evaluation of the work history should review frequency of job changes and reasons for each termination. Persons who are laid off from work are six times more likely to be violent than their employed peers (Catalano et al. 1993).

MENTAL DISORDERS AND VIOLENCE

Substance use and violence risk

Illicit drugs and alcohol are strongly associated with violent behavior (Monahan et al. 2001; Pulay et al. 2008). The majority of persons involved in violent crimes are under the influence of alcohol at the time of the act (Murdoch et al. 1990). Furthermore, nearly 90% of intravenous drug users have committed a violent offense (Darke et al. 2010). Stimulants, such as cocaine, crack, amphetamines, and PCP are of particular concern.

Research indicates that methamphetamine use is particularly problematic. Over 25% of methamphetamine users experience psychosis; clinically significant hostility was more common with severe psychotic symptoms that lasted longer than 2 days (McKetin et al. 2008). In their study of 278 methamphetamine users who did not meet criteria for schizophrenia or bipolar disorder, McKetin et al. (2014) found that violent behavior was over six times more likely when patients were using methamphetamine compared to when they were not. In addition, this increased risk was dose dependent, with heavier use (16 or more days in the past month) producing a 15-fold increase in violent behavior. For intravenous drug users, two factors are associated with future violent offending: having committed violence under the influence and having more impulsive personality traits (Torok et al. 2014).

Although persons with an alcohol or substance use disorder are more than twice as likely as those with schizophrenia to report violent behavior in the past year, substance use comorbid with a mental disorder poses an even greater risk of future violence than either condition alone (Swanson et al. 1990). Moreover, the comorbidity of substance use accounts for a significant portion of the violence committed by individuals with mental disorders (Monahan et al. 2001). Substance use may increase violence risk in individuals with mental illness through their acute pharmacological effects, the exacerbation of psychiatric symptoms, or resulting treatment nonadherence (Volavka and Swanson 2010). Evaluators should carefully review a person's substance use history and review any relationship of substance use to past mental health symptoms and/or aggressive behaviors. Screening questions to help evaluate the relationship of substances to aggression are provided in Table 60.1.

Psychosis and violence

Psychotic symptoms are particularly important to explore when conducting a violence risk assessment. In an analysis of 204 studies examining the relationship between psychopathology and aggression, Douglas et al. (2009) found that psychosis was the most important predictor of violent behavior. Recent research has indicated that even

Table 60.1 Substance use and violence screening questions

1. What effects does the substance have on you?
2. Has your substance use caused or worsened any type of mental health symptom?
3. Did you ever feel anger or aggression when using the substance?
4. Did you ever feel anger or aggression when withdrawing from the substance?
5. What is the most violent thing that you have done when using or withdrawing from the substance?
6. Do you have any legal charges related to your substance use?
7. Do you think it is likely you will continue to use alcohol or drugs?

individuals in the pre-psychotic states of their illness have a higher rate of criminal offending. For example, Purcell et al. (2015) determined that persons at risk for psychosis were significantly more at risk for being criminally charged and criminally convicted when compared to persons not identified as at risk for psychosis.

Delusions and command auditory hallucinations are among the most common psychotic symptoms that increase future dangerousness and therefore receive special attention in this chapter.

DELUSIONS AND VIOLENCE

The threat/control-override (TCO) type of delusions are characterized by the presence of beliefs that one is being threatened (e.g., being followed or poisoned) or that one is losing control to an external source (e.g., one's mind is dominated by forces beyond one's control) (Link and Stueve 1995). Swanson and colleagues (1996), using data from the Epidemiologic Catchment Area surveys, found that people who reported TCO symptoms were about twice as likely to engage in assaultive behavior as those with other psychotic symptoms.

In contrast, results from the MacArthur Study of Mental Disorder and Violence (Monahan et al. 2001) showed that the presence of delusions did not predict higher rates of violence among recently discharged psychiatric patients. In particular, a relationship between the presence of TCO delusions and violent behavior was not found. In a study comparing male criminal offenders with schizophrenia found not guilty by reason of insanity to matched controls of nonoffending individuals with schizophrenia, Stompe et al. (2004) also found that TCO symptoms showed no significant association with the severity of violent behavior. The prevalence of TCO symptoms also did not differ between the two groups. However, nondelusional suspiciousness, such as misperceiving others' behavior as suggesting hostile intent, has demonstrated a relationship with violence (Monahan et al. 2001).

Nederlof et al. (2011) conducted a cross-sectional multicenter study to further examine whether the experience of TCO symptoms is related to aggressive behavior. The study sample included 124 psychotic patients characterized by the following diagnostic categories: 70.2% paranoid schizophrenia; 16.1% "other forms" of schizophrenia; 3.2% schizoaffective disorder; 0.8% delusional disorder; and 9.7% psychosis not otherwise specified (NOS). These researchers developed the Threat/Control-Override Questionnaire (TCOQ), a 14-item self-report scale designed to measure both delusional threat and control-override symptoms in a more detailed manner than in previous research. The six *Threat* items specific to this instrument are as follows (Nederlof et al. 2011):

- Other people have tried to poison me or to do me harm.
- Someone has deliberately tried to make me ill.
- Other people have been secretly plotting to ruin me.
- Someone has had evil intentions against me.
- I have the thought that I was being followed for a special reason.
- People have tried to drive me insane.

The eight *Control-Override* items on the TCOQ are as follows (Nederlof et al. 2011):

- I am under the control of an external force that determines my actions.
- Other people control my way of movements.
- Other people can insert thoughts into my head.
- My thoughts are dominated by an external force.
- I have the feeling that other people can determine my thoughts.
- Other people can insert thoughts into my mind.
- I have the feeling that other people have control over me.
- My life is being determined by something or someone other than myself.

The authors determined that TCO symptoms were a significant correlate of aggression in their study sample. When the two domains of TCO symptoms were evaluated separately, only threat symptoms significantly contributed to aggressive behavior. In their attempt to reconcile conflicting findings from earlier research regarding the relationship of TCO symptoms to aggressive behavior, the authors suggested that various methods of measuring TCO symptoms may underlie the seemingly contradictory findings among various studies (Nederlof et al. 2011).

In addition to research examining the potential relationship of particular delusional content to aggression, Appelbaum et al. (1999) utilized the MacArthur–Maudsley Delusions Assessment Schedule to examine the contribution of non-content-related delusional material to violence. The seven dimensions covered by the MacArthur–Maudsley Delusions Assessment Schedule (with brief definitions) are as follows:

1. *Conviction*: The degree of certainty about the delusional belief.
2. *Negative affect*: Whether the delusional belief makes the individual unhappy, frightened, anxious, or angry.
3. *Action*: The extent to which the individual's actions are motivated by the delusional belief.
4. *Inaction*: Whether the individual has refrained from any action as a result of the delusional belief.
5. *Preoccupation*: The extent to which the individual indicates that his or her thoughts focus exclusively on the delusion.
6. *Pervasiveness*: The degree to which the delusional belief penetrates all aspects of the individual's experiences.
7. *Fluidity*: The degree to which the delusional belief changed frequently during the interview.

These authors found that individuals with persecutory delusions had significantly higher scores on the dimensions

of "action" and "negative affect," indicating that persons with persecutory delusions may be more likely to react in response to the dysphoric aspects of their symptoms (Appelbaum et al. 1999). Other research has demonstrated that individuals suffering from persecutory delusions and negative affect are more likely to act on their delusions (Buchanan et al. 1993) and to act violently (Cheung et al. 1997).

COMMAND HALLUCINATIONS AND VIOLENCE

An evaluator should carefully assess if the person is experiencing auditory hallucinations when determining violence risk. Auditory command hallucinations are experienced by approximately half of psychiatric patients who experience auditory hallucinations (Shawyer et al. 2003). Because many patients do not report their command hallucinations to others, the frequency of these hallucinations is likely even higher (Zisook et al. 1995). The majority of command hallucinations are nonviolent in nature. Individuals are more likely to obey nonviolent commands than violent commands (Chadwick and Birchwood 1994). However, between 30% and 65% of individuals comply with commands to harm others (Shawyer et al. 2003; Fox et al. 2004).

Research establishing specific factors associated with persons acting on harm-other command hallucinations has been mixed. In a review of seven controlled studies examining the relationship between command hallucinations and violence, no study demonstrated a positive relationship between command hallucinations and violence; one found an inverse relationship (Rudnick 1999). In contrast, McNiel et al. (2000) found in their study of 103 civil psychiatric inpatients that 33% of patients reported having experienced command hallucinations to harm others during the prior year, and 22% of the patients reported that they complied with such commands. The authors concluded that study subjects who experienced command hallucinations to harm others were more than twice as likely to be violent than those without such commands.

Four factors have been described as increasing a person's willingness to comply with harm-other command hallucinations. First, persons are more likely to act on auditory hallucinations to harm others when they perceive the voice as powerful (Fox et al. 2004; Shawyer et al. 2008). Birchwood and Chadwick (1997) noted that persons who perceive a voice as powerful experience a subjective loss of control over the voice, with associated feelings of powerlessness and helplessness. Evaluators should ask the individual what he or she believes would be the consequence for failing to obey the voice, recognizing that direr perceived outcomes increase compliance (Barrowcliff and Haddock 2010). Second, individuals who have a positive appraisal of a harm-other hallucination are more likely to act when compared to individuals who interpret the voice as threatening. In other words, if the person believes that following the directive of the command hallucination will benefit him or her, that person is more likely to comply (Shawyer et al. 2008). Third, persons are more likely to follow harmful command hallucinations when they are associated with a congruent delusion (Shawyer et al. 2008). As an example, a person who hears a voice to kill his wife is more likely to act on this command if he has the delusional belief that his wife has been invaded by an evil alien who is preparing to kill him. Finally, Cheung et al. (1997) noted in their study of patients with schizophrenia that those whose hallucinations generated negative emotions (e.g., anger, anxiety, and sadness) were more likely to act violently than those individuals with voices that generated positive emotions.

When evaluating a patient with persecutory delusions, the clinician should also inquire if the patient has employed "safety actions." Safety actions are specific behaviors (such as avoidance of a perceived persecutor or escape from a fearful situation) that the individual has employed with the intention of minimizing a misperceived threat. In one study of 100 patients with persecutory delusions, over 95% reported using safety behaviors in the past month. In this study, individuals with a prior history of violence reported a greater ongoing use of safety behaviors (Freeman et al. 2007).

SCHIZOPHRENIA AND VIOLENCE RISK

Delusions and hallucinations are prominent symptoms of schizophrenia, and there is evidence that a diagnosis of schizophrenia is associated with an increase in criminal offending. In a retrospective review of 2861 Australian patients with schizophrenia followed over a 25-year period, Wallace, Mullen, and Burgess (2004) found that individuals with schizophrenia were significantly more likely to have been convicted of a criminal offense (including violent offenses) relative to matched controls. These authors noted that the criminal behaviors committed by individuals with schizophrenia could not be entirely accounted for by comorbid substance use, active symptoms, or characteristics of systems of care (Wallace et al. 2004). Fazel et al. (2014) determined that over 10% of men diagnosed with schizophrenia were convicted of a violent offense within 5 years of their diagnosis. In individuals diagnosed with schizophrenia, investigation of prior violent convictions is particularly important. In their study of nearly 14,000 individuals with two or more hospitalizations for schizophrenia treatment, Witt, Lichtenstein, and Fazel (2015) found that conviction for a violent crime prior to a diagnosis of schizophrenia was the strongest predictor of subsequent violence.

A typology of three groups indicates different pathways to violence among individuals with schizophrenia. The first group includes persons with a history of childhood conduct disorder who demonstrate aggressive behavior and antisocial acts before and after being diagnosed with schizophrenia. The second group becomes involved in aggressive behavior concomitant with the onset of their illness. The third group involves individuals with schizophrenia who engage in a physical assault after many years of their illness, i.e., a "late first offender" (Hodgins et al. 2014). Van Dongen et al. (2014) found that although persecutory delusions were associated with all three groups, they were more likely to be associated in the late first offender group.

Mood disorders and violence risk

Most studies examining the relationship between mood disorders and violence have not differentiated between bipolar disorder, mania, and depression (Graz et al. 2009). To evaluate if criminal behavior and violent crimes were more common in the diagnosis of depression versus mania, Graz et al. (2009) examined the national crime register for 1561 patients with an affective disorder who had been released into the community. The rate of criminal behavior and violent crimes was highest in the bipolar disorder group (15.7%) compared to patients in the major depressive disorder group (1.4%). The authors concluded that different mood disorders have different violence risk. Other studies have examined violence risk factors unique to different mood disorders, as summarized below.

DEPRESSION AND VIOLENCE

Depression may result in violent behavior, particularly in depressed individuals who strike out against others in despair. After committing a violent act, the depressed person may attempt suicide. Depression is the most common diagnosis in murder–suicides (Marzuk et al. 1992). Studies examining mothers who kill their children (filicide) have found that they were often suffering with severe depression. High rates of suicide following a filicide have been noted, with between 16% and 29% of mothers and 40% and 60% of fathers taking their life after murdering their child (Rodenburg 1971; Marzuk et al. 1992; Hatters-Friedman et al. 2005). In a study of 30 family filicide–suicide files, the most common motive involved an attempt by the perpetrator to relieve real or imagined suffering of the child, a category known as an altruistic filicide. Eighty percent of the parents studied had evidence of a past or current psychiatric history, with nearly 60% suffering from depression, 27% with psychosis, and 20% experiencing delusional beliefs (Hatters-Friedman et al. 2005).

In their analysis of 386 individuals from the MacArthur Violence Risk Assessment Study with a categorical diagnosis of depression, Yang et al. (2012) noted two important findings relevant to depression and future violence risk. First, violence that had occurred within the past 10 weeks was a strong predictor of violence by participants with depression, but not by participants with a psychotic disorder. This finding suggests that a past history of *recent* violence may represent a higher risk of future violence in depressed patients than in those with psychosis. Second, this risk of future harm by depressed patients was further increased with alcohol use.

BIPOLAR DISORDER AND VIOLENCE

Patients with mania show a high percentage of assaultive or threatening behavior, but serious violence is rare (Krakowski et al. 1986). Patients with mania most commonly exhibit violent behavior when they are restrained or have limits set on their behavior (Tardiff and Sweillam 1980).

Active manic symptoms have been suggested as playing a substantial role in criminal behavior. In particular, Fazel et al. (2010) compared violent crime convictions for over 3700 individuals diagnosed with bipolar disorder with general population controls and unaffected full siblings. This longitudinal study had two main findings. First, although individuals with bipolar disorder exhibited an increased risk for violent crime compared to the general population, most of the excess violent crime was associated with substance abuse comorbidity. Second, unaffected siblings also had an increased risk for violent crime, highlighting the contribution of genetics or early environmental factors in families with bipolar disorder.

Cognitive impairment and violence

The risk of violence increases for those with cognitive impairment (Quinsey and Maquire 1986; Borum et al. 1996). Brain injury has also been associated with aggressive behavior. After a brain injury, individuals may become verbally and physically aggressive (National Institutes of Health 1998). Characteristic features of aggression resulting from a brain injury include reactive behavior triggered by trivial stimuli, lack of planning or reflection, nonpurposeful action with no clear aims or goals, explosive outbursts without a gradual buildup, an episodic pattern with long periods of relative calm, and feelings of concern and remorse following the episode.

Epilepsy has also been described as having a relationship to violence. However, the evidence for this relationship has focused primarily on small samples of incarcerated individuals or children with epilepsy (Fazel et al. 2011). In their study of 22,000 individuals with traumatic brain injury and 22,000 individuals with epilepsy, Fazel et al. (2011) evaluated whether persons with either of these disorders were at an increased risk for violent crime compared with the general population or unaffected siblings. The authors reported several important findings. First, individuals with traumatic brain injury had a significantly increased risk of violent crime, particularly in cases involving focal brain injuries and injury after age 16. Second, after adjusting for familial factors, epilepsy was not associated with an increased risk of violent crime. Therefore, although evaluators should consider traumatic brain injury a risk factor for future violence, such causality does not appear to be established for epilepsy (Fazel et al. 2011).

PERSONALITY FACTORS AND VIOLENCE RISK

The most common personality disorder associated with violence is antisocial personality disorder (ASPD) (Monahan et al. 2001). The violence by those with antisocial personality disorder is often motivated by revenge, or occurs during a period of heavy drinking. Violence among these persons is frequently cold and calculated and lacks emotionality (Williamson et al. 1987). In addition to a *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*) diagnosis of antisocial personality disorders or

traits, the clinician should be familiar with the psychological construct known as psychopathy. The term *psychopath* was described by Cleckley (1976) as an individual who is superficially charming, lacks empathy, lacks close relationships, is impulsive, and is concerned primarily with self-gratification. Hare and colleagues developed the Psychopathy Checklist-Revised (PCL-R) (Hare 1991) as a validated measure of psychopathy in adults. Psychopathy is a strong predictor of general criminal behavior and violence among adults (Salekin et al. 1996). Psychopathy is more predictive of violence than a *DSM-5* diagnosis of ASPD.

ASSESSING CURRENT DANGEROUSNESS

When conducting an assessment of current dangerousness, play close attention to the individual's affect. Individuals who are angry and lack empathy for others are at increased risk for violent behavior (Menzies et al. 1985). In their meta-analysis of 610 individuals, Reagu et al. (2013) found a consistent and significant association between angry affect and violent behavior in the context of psychotic illness.

All threats should lead to clinicians attempting to gather additional details. An important line of inquiry involves understanding the exact relationship to an intended victim. Understanding how a violent act would be carried out and the expected consequences for the individual voicing the threat helps the clinician assess the degree of danger. In addition, fully considering the consequences of an act may help the individual elect an alternative coping strategy. For example, a man may be focused on revenge against his wife because of her infidelity. When confronted with the likelihood of spending many years in prison, he may decide to divorce his wife instead. Additional information that should be elicited includes potential grudge lists and an investigation of the subject's fantasies of violence (Monahan et al. 2001).

The clinician should also assess the suicide risk in any patient making a homicidal threat. One study found that 91% of outpatients who had attempted homicide also had attempted suicide and that 86% of patients with homicidal ideation also reported suicidal ideation (Asnis et al. 1997). In their study of 1460 adults with schizophrenia, Witt et al. (2014) found that suicidal threats were independently associated with violence risk in both males and females.

Inquiring about access to a weapon is particularly important in evaluating a person's risk for imminent dangerousness. A person who has used weapons against others in the past has an increased risk of future violence. The main difference between assault and homicide is the lethality of the weapon used. Loaded guns have the highest lethality of any weapon. An assault with a gun is five times more likely to result in a fatality than an attack with a knife (Zimring 1991). The recent movement of a weapon, such as transferring a gun from a closet to a nightstand, may be particularly ominous in a paranoid person. In general, the greater the fear, the more likely the paranoid person is to kill someone he misperceives as a persecutor.

Finally, the evaluator should ask the person to rate his or her own likelihood of future violence. Roaldset and Bjorkly (2010) asked 489 patients admitted to a psychiatric hospital to rate their risk of future threatening or violent actions toward others. Moderate or high-risk scores on self-ratings of future violence remained significant predictors of violence 1 year post-discharge. However, persons who rated themselves as "no risk" or refused to answer the question also had a considerable number of violent episodes, indicating that a self-report of low risk of violence may produce false-negatives.

When organizing strategies to decrease risk factors related to future violence, clinicians should distinguish static from dynamic risk factors. By definition, static factors are not subject to change by intervention. Static factors include such items as demographic information and past history of violence. Dynamic factors are subject to change with intervention and include such factors as access to weapons, acute psychotic symptoms, active substance use, and the person's living situation. Clinicians may find it helpful to organize a chart that outlines violence risk factors, management and treatment strategies to address dynamic risk factors, and the current status of each risk factor. This approach will assist in the development of a violence prevention plan that addresses the unique combination of risk factors for a particular patient and organizes interventions to manage those risks.

SUMMARY

Clinicians and forensic evaluators are requested to conduct violence risk assessments in a variety of situations. A structured clinical assessment approach is an important component of assessing future dangerousness.

SUMMARY KEY POINTS

- Although the majority of individuals with mental illness are not violent, specific interventions can be focused to help decrease violence risk.
- Alcohol and illicit drug use are among the greatest risk factors for aggression.
- Psychotic symptoms are associated with an increase in violence risk, particularly those with paranoia and suspiciousness.
- Individuals with mental illness who experience fear and anger are at a heightened risk of becoming violent.
- Identifying dynamic risk factors for future violence is important for developing a plan to help address and reduce violence risk.

Clinical management of aggression and violence

WILLIAM NEWMAN AND KENNETH TARDIFF

INTRODUCTION

This chapter addresses the management of adults with aggressive and violent behaviors related to major psychiatric disorders. The chapter reviews many evidence-based treatment options, with a focus on particular diagnoses that are associated with aggression. The classifications of the disorders are consistent with diagnostic criteria in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*, American Psychiatric Association 2013). The conditions are presented in the order addressed in the *DSM-5*, based on the order of development throughout the lifetime.

There is not currently a U.S. Food and Drug Administration (FDA)-approved pharmacological treatment of aggression. The treatments used to target aggression (beyond primary treatment of psychiatric disorders) are therefore off label and should be carefully considered after reviewing the available evidence. This chapter presents some of the existing evidence supporting off-label pharmacological treatments targeting aggression.

NEURODEVELOPMENTAL DISORDERS

Individuals with intellectual disability (formerly mental retardation in *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision [*DSM-IV-TR*]) can display aggressive behaviors due to a variety of factors, including impaired impulse control, difficulty with long-term planning, and trouble handling stressful and emotional situations. Pharmacological treatments have shown some benefits in curbing aggressive behaviors in this population. Because much of the published evidence uses the *DSM-IV-TR* definition of "mental retardation," the term *cognitive impairment* will be employed throughout the remainder of this section for the sake of simplicity.

Treatment with lithium has proven beneficial in managing aggressive behaviors in this population, with suggested target lithium levels ranging from 0.5 to 1 mEq/L (Tyrer et al. 1984; Craft et al. 1987; Spreat et al. 1989). Treatment with valproate has also proven beneficial in managing aggression in individuals with cognitive impairment (Mattes 1992). Treatment with antipsychotic medications can also help manage aggressive behaviors (Amore et al. 2011). Risperidone in particular has displayed clear benefits in this population, generally at doses ranging from 0.5 to 4 mg/day (Hasler and Reis 2010). Beta blockers have also shown benefits in curbing aggression in patients with cognitive impairment (Ruedrich et al. 1990).

Nonpharmacological interventions have been employed to help curb aggressive behaviors in individuals with cognitive impairment, including psychotherapy and structured teaching. Behavioral skills training is one intervention that has especially shown promise (Travis and Sturmey 2013). Applied behavioral analysis (ABA) is another technique that has been tried in patients with cognitive impairment. However, the data to this point regarding the benefits of ABA for improving aggression have been equivocal (Aman et al. 1985; Hassiotis et al. 2011; Hassiotis et al. 2012).

SCHIZOPHRENIA SPECTRUM AND OTHER PSYCHOTIC DISORDERS

The primary pharmacological treatment of schizophrenia is with typical or atypical antipsychotic medications. In the management of acute agitation, antipsychotic medications can be administered orally or intramuscularly to address current or impending aggressive behaviors. Clozapine treats psychosis as well, but unlike other antipsychotic medications, clozapine has been shown to directly reduce long-term violence, even after controlling for sedation (Chiles et al. 1994; Citrome et al. 2001). Close, consistent laboratory testing is essential for following blood levels and monitoring for potential side effects of clozapine.

Table 61.1 Dosing information for common long-acting injectable antipsychotics

Name	Typical dosing range	Typical frequency	Half-life (t 1/2)	Other notes
Prolixin Decanoate	12.5–50 mg (increments of 6.25)	q2–3 weeks	15 days	Usually give test dose of 6.25 mg after patient tolerates oral Prolixin
Haldol Decanoate	25–300 mg (increments of 25)	q3–4 weeks	21 days	Usually dosed 10–15 times oral dose; max initial test dose of 100 mg
Risperdal Consta	25–50 mg (increments of 12.5)	q2 weeks	3–6 days	Usually does not reach steady state until 8 weeks after first injection
Invega Sustenna	39–234 mg (increments of 39)	q1 month	25–49 days	Initiation dose of 234 mg on day 1; maintenance dose on day 8 (±2 days)
Zyprexa Relprevv	150, 210, 300, 405 mg (see dosing recs)	q2–4 weeks	30 days	Requires monitoring for post-injection delirium/sedation syndrome (PDSS)
Abilify Maintena	400 mg (also comes in 300 mg)	q1 month	30–47 days	Single, 400 mg injection usually used for initiation and maintenance
Invega Trinza	273, 410, 546, 819 mg (see dosing recs)	q3 months	84–139 days	Initiated only after treatment with Invega Sustenna for at least 4 months
Aristada	441, 662, 882 mg (see dosing recs)	q1 month	29–35 days	Continue administering oral Abilify for 21 consecutive days

Some patients have a history of limited adherence to daily antipsychotic medications, which can result in untreated psychotic symptoms. In cases involving limited adherence, long-acting injectable medications can be administered periodically to ensure adherence and maintain therapeutic blood levels. Table 61.1 lists dosing instructions for commonly used long-acting injectable medications currently on the market. Depending on the location of the individual, the patient may voluntarily consent to treatment with long-acting injectable medications, have a substituted decision maker decide on his or her behalf, or be court ordered to continue receiving treatment.

Mood stabilizers can be used to treat residual aggressive behaviors for individuals with schizophrenia who do not respond to antipsychotic medications alone (McEvoy et al. 1999). Valproate (Dose et al. 1998) and carbamazepine (Okuma et al. 1989) have specifically been found to decrease aggressive behaviors by individuals who are also on antipsychotic medications. Lithium (Bender et al. 2004) and lamotrigine (Pavlovic 2008) prescribed in conjunction with clozapine have been shown to decrease aggression as well. However, the effects of lithium in combination with other antipsychotics have not been as well supported in the literature (Collins et al. 1991; Wilson 1993). Benzodiazepines can be used as adjunct treatment with antipsychotic medications to reduce aggressive behaviors, particularly in individuals who do not have a history of substance abuse (McEvoy et al. 1999).

In addition to medications, individuals with schizophrenia can be exposed to nonpharmacological treatment to assist them in adapting to their surroundings. Therapy should be aimed at both supporting the individual and helping to ensure medication adherence. Supportive therapy is one of the most commonly employed techniques with patients who have schizophrenia, though the outcomes are somewhat equivocal overall and have not shown direct benefits for aggression (Buckley et al. 2015). There is, however, evidence that cognitive behavioral therapy (CBT) may specifically improve aggression in patients with schizophrenia (Haddock et al. 2009; Rathod et al. 2010).

BIPOLAR AND RELATED DISORDERS

Aggressive behaviors by manic individuals are often impulsive and related to their elevated mood, grandiosity, or sense of invulnerability. The primary intervention is therefore treatment of the mania. Treatment involves the daily use of a mood stabilizer, such as lithium or valproate, with the potential addition of an antipsychotic when there are concurrent psychotic symptoms. Regarding combination treatment for individuals with mania and psychosis, the American Psychiatric Association (APA) Practice Guidelines note, "The *combination* [emphasis included] of an antipsychotic with either lithium or valproate may be more effective than any of these agents alone. Thus, the first-line pharmacological treatment for patients with severe mania is the initiation of either lithium plus an antipsychotic or valproate plus an antipsychotic" (APA 2002, 16).

Aggressive behaviors are often the precipitating factor leading manic patients to be hospitalized or arrested. Which outcome occurs frequently remains up to the discretion of the responding officer. Patients with bipolar disorder are at an overall increased risk of being arrested. In one study of individuals with bipolar disorder who had been arrested, the majority were manic (74.2%) and/or psychotic (59%) at the time of their arrest (Quanbeck et al. 2004). The presence of psychosis or comorbid substance use can further increase their risk of aggression (Asnis et al. 1997).

Nonpharmacological interventions center on educating the patient and the family about ways to help prevent, or at least recognize, manic episodes. Although early signs differ for individual patients, sleep changes are commonly noticed preceding a manic episode. Identifying warning signs can allow the patient or family to contact the treating provider and initiate changes to the treatment plan, as necessary. This exercise can improve communication, as well as the overall relationship between the provider, the patient, and the family (Perry et al. 1999).

DEPRESSIVE DISORDERS

Similar to bipolar disorder, the most important factor in preventing aggression in patients with major depressive disorder involves adequately treating the symptoms. Antidepressants are the first-line treatment. Most prescribers start with selective serotonin reuptake inhibitors (SSRIs) due to their favorable side effect profile. In patients experiencing psychotic symptoms as part of their depression, treatment with an antipsychotic should be added. According to the APA Practice Guidelines, "For patients who exhibit psychotic symptoms during an episode of major depressive disorder, treatment should include a combination of antipsychotic and antidepressant medications" (APA 2010, 20).

Some have suggested that taking SSRIs may itself be associated with violence (Mason 2002; Healy et al. 2006; Moore et al. 2010). The cases reported in those articles have involved extreme acts of violence, including homicide. Other authors have held that there is no association between violence and the use of SSRIs (Tardiff et al. 2002; Barber et al. 2008). In seemingly the most extensive study published thus far, Bouvy and Liem (2012) presented data from their 15-year analysis that tracked patients in the Netherlands. From their data, the authors reported a negative association between antidepressants and lethal violence. Based on the existing literature, there does not appear to be a clearly proven link between SSRIs and violent behavior.

There are relatively uncommon, though devastating, acts that are most often seen in the setting of depression. Murder–suicide is one act that is commonly linked to depression. Depending on the source, murder–suicide can be defined as committing suicide within 1 day to 1 week of killing another person (Marzuk et al. 1992; Bossarte et al. 2006). Marzuk and colleagues (1992) proposed a classification system for murder–suicide involving a combination of the perpetrator's relationship to the victim and the perpetrator's presumed motive. Of the five major types described by Marzuk and colleagues, the Consortial–Possessive type accounts for 50%–75% of murder–suicides (Marzuk et al. 1992). The Consortial–Possessive type involves ex-intimate partners seeking revenge. Depression is highly linked to the act of murder–suicide (Eliason 2009).

Another rare, though devastating, event associated with depression involves filicide, the murder of a child. More specific terms including neonaticide (murder of infant in first 24 hours) and infanticide (typically defined as murder of children under 1 year old) have been defined (Friedman et al. 2012). As with murder–suicide, there is a strong link between depression and filicide (Friedman et al. 2005; Razali et al. 2015; Shields et al. 2015). Screening and education have been proposed as measures to help prevent the potentially devastating effects of perinatal depression (Rhodes and Segre 2013).

Murder–suicide and filicide are both very rare events. Because both events are linked to depression, clinicians can best help prevent these tragedies through providing adequate treatment and thorough screenings of depressed patients for risk to others (in addition to asking about suicidality). In some instances, patients with depression may need to be hospitalized if there is concern about potential harm to others.

TRAUMA- AND STRESSOR-RELATED DISORDERS

Posttraumatic stress disorder (PTSD) is the trauma- and stressor-related disorder most often associated with aggression. Combat exposure and the level of PTSD symptoms have been associated with aggression and related legal problems in veterans (Wilson and Zigelbaum 1983; Miles et al. 2015). In one study, veterans hospitalized psychiatrically were seven times more likely to have committed an act or acts of violence in the preceding 4 months (McFall et al. 1999). Clinicians interacting with PTSD patients who either present agitated or have a known history of violence should consider asking questions relevant to violence risk assessment.

There are no specifically identified pharmacological treatments proven to effectively target aggression in PTSD. Schoenfeld and colleagues (2004) wrote a general overview presenting evidence for various pharmacological treatments of PTSD. The treatment of PTSD with benzodiazepines is worth specific mention. Studies have reported a range of 30.4%–73.7% of PTSD patients who are being prescribed benzodiazepines (Harpaz-Rotem et al. 2008; Lund et al. 2013). This fact is important because other reports have demonstrated an association between benzodiazepines prescribed for PTSD and related aggression (Kosten et al. 2000; Shin et al. 2012). One recent review concluded that benzodiazepines should be relatively contraindicated in patients with PTSD due to the worsening of aggression (Guina et al. 2015).

As with the pharmacological approaches, there is no psychotherapeutic modality that has been clearly demonstrated to specifically target aggression in patients with PTSD. CBT has proven most effective in addressing general symptoms of PTSD (Ursano et al. 2004). Virtual reality exposure therapy (VRET) is another emerging treatment option to address the general symptoms of PTSD (Goncalves et al. 2012). However, neither CBT nor VRET have been

systematically studied regarding their impact on aggression in this population.

DISRUPTIVE, IMPULSE-CONTROL, AND CONDUCT DISORDERS

Intermittent explosive disorder (IED) by definition involves the patient exhibiting aggressive behavior. The violence is grossly out of proportion to any provocation or precipitating stressor. The violent episodes are generally not premeditated but rather are impulsive in nature. The patient may describe the violent episodes as spells or attacks in which the violence is preceded by a sense of tension or arousal and is followed by a sense of relief. The concept of IED as a separate entity has faced criticism over the years, particularly due to the ambiguities of the diagnosis and lack of diagnostic validity when using the *DSM-IV* criteria. However, recent studies have shown improved validity when applying *DSM-5* criteria (Coccaro 2012).

The first step of addressing IED involves excluding other potential diagnoses, including personality disorders, which are often associated with aggression. There are pharmacological interventions that have been reported as effective for decreasing the amount of aggression in patients with IED. Some of the medications found beneficial in select populations include fluoxetine, clozapine, and some mood stabilizers (Kant et al. 2004; Coccaro et al. 2009; Jones et al. 2011). CBT has been demonstrated as an effective intervention for individuals with IED (Gavolski and Blanchard 2002).

SUBSTANCE-RELATED AND ADDICTIVE DISORDERS

Substance use is often comorbid with conditions such as psychotic disorders, mood disorders, and personality disorders (particularly Cluster B). Substance use can considerably complicate the management of aggression, particularly when it is downplayed or not volunteered by individuals. Several studies have reflected the increased rates of aggression in individuals with comorbid mental health and substance use diagnoses (Swanson et al. 1990; Swanson et al. 1996; Johns 1997; Steadman et al. 1998). Targeting substance use treatment is a major aspect of managing aggressive patients. Many substances decrease the ability to plan actions and respond to dangerous situations. Addressing substance use issues can help limit the chance that individuals become victims or perpetrators of violent acts.

Alcohol has a very well-established association with violence. The number of establishments serving alcohol in a geographical region correlates highly with violence (Cameron et al. 2015). Studies have also shown that, on average, perpetrators of violent crimes have higher blood alcohol levels than perpetrators of nonviolent crimes (Langevin et al. 1982; Murdoch et al. 1990). This finding is consistent with the disinhibition resulting from acute alcohol intoxication. Alcohol impairs various regions of the brain, most importantly the prefrontal cortex, which results in individuals acting more impulsively and having a limited ability to make well-reasoned decisions.

Interestingly, evidence clearly linking other substances of abuse to violence is less apparent. Alcohol is the only substance of abuse clearly established to increase aggression in animal studies (Roth 1994). In humans, several substances of abuse are commonly associated with increased aggression, including phencyclidine, cocaine, opioids (primarily during withdrawal), and amphetamines (methamphetamine, "bath salts," etc.). This disparity seemingly stems from the fact that much of the violence related to substances of abuse occurs during the process of procuring or distributing the substances (Roth 1994).

Synthetic amphetamines (aka "bath salts") have received a lot of media attention over recent years. They have been linked with acts of extreme violence, including unusual "zombie" attacks (John et al. 2014; Vazirian et al. 2015). Evidence reflects that bath salts are highly addictive. In rat studies, the animals exerted nearly four times the effort to get bath salts than to get methamphetamine (Aarde et al. 2013). However, there are still no conclusive animal studies demonstrating that bath salts are directly linked to aggression. The combination of bath salts being highly addictive and potentially contributing to violent behavior makes them an important substance for clinicians to ask their patients about during clinical assessments.

NEUROCOGNITIVE DISORDERS

Neurocognitive disorder due to traumatic brain injury (TBI)

Aggression is an issue that clinicians frequently encounter when managing patients with acquired brain injuries. In the *DSM-5*, the condition is referred to as neurocognitive disorder due to traumatic brain injury. Various medications have been prescribed over the years attempting to target aggression in this population. Beta blockers present one effective strategy for specifically targeting aggression in patients with acquired brain injuries. The published research, though largely limited to small studies, has been encouraging. One research group published reports involving double-blind, placebo-controlled studies relating the benefits of beta blockers for individuals with acquired brain injuries (Greendyke and Kanter 1986; Greendyke et al. 1986, 1989).

Most of the published studies involving beta blockers for the management of aggression have used propranolol and pindolol. Many of the doses utilized in early studies were at higher doses than are even typically prescribed for antihypertensive effects. At the significantly higher doses, there were frequent reports of adverse events related to drops in heart rate and blood pressure. Recent studies have also found encouraging anti-aggressive effects using lower doses

of beta blockers. For instance, Caspi et al. (2001) showed positive outcomes from treatment with pindolol 5 mg three times a day.

Some researchers have specifically chosen to study pindolol due to it displaying intrinsic sympathomimetic activity (ISA), a partial agonism seen particularly at higher doses. The ISA results in less problematic drops in heart rate and blood pressure than might be experienced with propranolol. Pindolol also comes in a generic formulation and can be easily titrated in patients whose vital signs and medical histories make them appropriate candidates.

Reports of other pharmacological treatment options for patients with acquired brain injuries have also appeared in the literature. Mood stabilizers are the other class that has shown significant benefits in this population. Multiple studies have reported the benefits of valproate to curb aggression in patients with acquired brain injuries (Geracioti 1994; Horne and Lindley 1995; Wroblewski et al. 1997). Another article discusses an open trial study showing benefits of carbamazepine to address agitation and aggression in individuals with severe closed-head injuries (Azouvi et al. 1999). One published case report alludes to beneficial effects of lithium in a patient with an acquired brain injury who had not responded to either propranolol or haloperidol (Haas and Cope 1985). However, due to the increased sensitivity to side effects of lithium in patients with acquired brain injuries, lower doses should be prescribed (Hornstein and Seliger 1989).

Major and mild neurocognitive disorder

The group of conditions previously referred to as dementias are now referred to as major and mild neurocognitive disorders in the *DSM-5*. In this section, the term *dementia* will be used because it is used in most of the studies cited in this section.

Aggressive behavior is a common problem encountered in patients with dementia, particularly as symptoms progress. One study reported that aggression had been a problem in over half (57.2%) of the subjects (Hamel et al. 1990). The aggressive behaviors can become a major burden for caregivers, both at home and at long-term facilities. Aggression also significantly increases the likelihood of individuals eventually being institutionalized (O'Donnell et al. 1992; Balestreri et al. 2000). Other psychiatric symptoms such as hallucinations, delusions, and depression can further complicate the management of patients with dementia.

For aggression that seems related to disease-related psychotic symptoms, low-dose antipsychotics should be prescribed. The typical antipsychotic haloperidol has been prescribed to patients with dementia diagnoses for decades. Low doses of haloperidol (1–5 mg daily) have been shown to decrease aggression in individuals with dementia (De Deyn et al. 1999; Allain et al. 2000). Low doses of the atypical antipsychotic risperidone (0.5–2 mg daily) have similarly been shown to decrease aggression in this population (De Deyn et al. 1999; Katz et al. 1999). The published results regarding the use of other antipsychotics for aggression in patients with dementia have largely been equivocal. However, clinicians should consider the FDA's 2005 black box warning regarding cerebrovascular events with atypical antipsychotic use for dementia in elderly patients. In 2016, the FDA approved Nuplazid, an atypical antipsychotic, specifically for the treatment of psychotic symptoms in Parkinson's disease.

Other medications have been suggested to target aggression that is primarily impulsive in patients with dementia. Benzodiazepines have proven effective, given either alone or in combination with antipsychotics (Yudofsky et al. 1990). However, clinicians must remember that elderly individuals are more likely to experience adverse effects such as delirium, paradoxical agitation, and the usual side effects associated with benzodiazepines. Mood stabilizers (lithium, valproate, carbamazepine) and beta blockers have also been reported as beneficial in patients with dementia (Mellow et al. 1993; Kunik et al. 1994; Lott et al. 1995).

There are a number of nonpharmacological approaches to managing patients with dementia and other major and mild neurocognitive disorders. Frequent reorientation is one strategy that helps limit agitation and related aggressive behaviors. A wealth of information about addressing additional factors such as pain, hearing deficits, misperceptions, and other issues are detailed in a document published by the Alzheimer's Society at https://www.alzheimers.org.

PERSONALITY DISORDERS

Individuals diagnosed with personality disorders sometimes display aggressive behaviors related to their personality structure. Antisocial and borderline personality disorders are the two personality disorders most commonly linked to aggression. The link is significant enough that aggressive behavior is a *DSM-5* diagnostic criterion for both antisocial and borderline personality disorder (APA 2013). Substance misuse is also common in both populations and can exacerbate the frequency and severity of aggressive behaviors.

Individuals with personality disorders have been the subjects of various studies involving the pharmacological management of aggression. One double-blind, placebo-controlled study presented the positive effects of using valproate to target impulsive aggression in patients with Cluster B personality disorders. The subjects in the study were prescribed average daily doses of 1400 mg, with average serum valproate levels of 65.5 (Hollander et al. 2003). Another double-blind, placebo-controlled study presented the positive effects of using lithium to target impulsive aggression in incarcerated individuals with "nonpsychotic personality disorders," with serum lithium levels typically under 1 mEq/L (Sheard et al. 1976). Yet another double-blind, placebo-controlled study presented the positive effects of using fluoxetine to target impulsive aggression in patients with personality disorders (Coccaro and Kavoussi 1997).

No pharmacological intervention has shown to be as effective in the overall management of individuals with antisocial personality disorder. These individuals are often prone to display planned, predatory acts of aggression, for which there is not a helpful pharmacological intervention. Contingency management and behavioral strategies are most effective for limiting planned aggression. Impulsive aggression is also a common issue encountered with antisocial personality disorder. Some case studies have reported benefits of addressing impulsive aggression in patients diagnosed with antisocial personality disorder using quetiapine, risperidone, and propranolol (Hirose 2001; Walker et al. 2003; Newman and McDermott 2011). Since the publication of the case report involving quetiapine, abuse of that antipsychotic medication in correctional settings and psychiatric hospitals has become more prevalent and therefore must be considered.

Similar to with antisocial personality disorder, multiple studies have been published about pharmacological interventions targeting the impulsivity and anger that often contribute to individuals with borderline personality disorder perpetrating acts of impulsive aggression. One double-blind, placebo-controlled study reported significantly decreased anger in subjects with borderline personality disorder placed on 15 mg of aripiprazole a day (Nickel et al. 2006). Other articles have reported decreased anger in patients with borderline personality disorder using mood stabilizers including lamotrigine, topiramate, and valproate (Hollander et al. 2001; Nickel et al. 2004; Tritt et al. 2005; Loew et al. 2006; Stoffers et al. 2010). In addition to anger, another common trait in borderline personality disorder is impulsivity that contributes to aggressive behaviors. The same four medications that have shown to impact anger in this population also improved impulsivity (Hollander et al. 2001; Nickel et al. 2004; Tritt et al. 2005; Loew et al. 2006; Nickel et al. 2006; Reich et al. 2009; Stoffers et al. 2010).

Psychotherapy also has an important role in addressing aggressive behaviors in patients with personality disorders, particularly individuals with Cluster B personality disorders or traits. The psychotherapeutic interventions must be tailored to each individual (Gerhart et al. 2013). A full discussion of psychotherapeutic interventions targeting patients diagnosed with personality disorders is beyond the scope of this chapter.

SUMMARY

There is not a single strategy to manage aggression using pharmacological or nonpharmacological interventions. Much of the existing evidence, particularly regarding pharmacological interventions, derives from case reports and small studies. Larger, controlled studies would improve our understanding of the effectiveness of the interventions. There remains much to be learned about the management of violence and aggression through future research.

SUMMARY KEY POINTS

- There is not currently an FDA-approved pharmacological treatment of aggression.
- Individuals diagnosed with conditions associated with aggression may benefit from a combined pharmacological and nonpharmacological treatment plan.
- Based on the existing literature, there does not appear to be a clearly proven link between SSRIs and violent behavior.
- Reports have demonstrated an association between benzodiazepines prescribed for PTSD and related aggression.
- Alcohol has a very well-established association with violence.
- Many individuals with Cluster B personality disorders behave aggressively.

Mass murder

JAMES L. KNOLL, WILLIAM NEWMAN, AND BRIAN HOLOYDA

INTRODUCTION

This chapter focuses on mass murder, a topic that has received considerable media attention of late. Mass murder is typically defined in the literature as a single event involving four or more victims at one location (Burgess 2006). Though rare, mass murder is catastrophic and impacts affected communities for years.

MASS MURDER OVERVIEW

Despite increased media attention over recent years, mass murder is not a new phenomenon. News media have suggested that mass killings became "a part of American life" after Charles Whitman climbed onto a tower at the University of Texas and killed 16 total people, including his wife and mother earlier that day in their homes (Mass public shootings 2007).

There are several challenges that make systematically researching mass murder difficult. For one, the base rate of mass murder is relatively low. According to Schenk and colleagues (2014), of the 9,776,094 emergency medical services (EMS) responses in the 2010 National EMS Database, 14,504 were categorized as mass casualty incidents. That amounts to 0.15% of the total responses. Because some responses involved multiple calls related to the same incidents, the 14,504 total calls involved 9913 unique incidents.

Furthermore, few perpetrators survive to explain their rationale. Perpetrators of mass murder generally differ from serial murderers, who kill a series of individual victims over an extended period. Unlike serial murderers, who can be very challenging for law enforcement to apprehend, mass murderers are more likely to be apprehended during or soon after commission of the crime (Burgess 2006). Many go into the situation expecting to be apprehended, be killed by law enforcement, or commit suicide (Fox and Levin 2003). Those who do survive may not be forthcoming about the thoughts that motivated their behavior, potentially driven by the desire to mitigate criminal responsibility (Declercq and Audenaert 2011).

Some data have been compiled about recent incidents involving "active shooters." The Federal Bureau of Investigation (FBI) published findings in 2014 designed to help prepare government agencies for active shooter incidents (Blair and Schweit 2014). To prepare the document, the authors reviewed all active shooter incidents in the United States between the years 2000 and 2013. They reviewed 160 total incidents, in which 486 individuals were killed and another 557 were wounded. These figures did not include the shooters. Of the 160 incidents, 64 (40%) fell within the federal definition of "mass killing"—defined as "three or more" victims killed. The FBI's findings showed that all but two incidents involved a single shooter. In 64 of the 160 incidents (40%), the shooters committed suicide either at the scene or soon thereafter. The majority of the incidents occurred at sites the FBI classified as areas of commerce (45.6%), educational environments (24.4%), or government properties (10.0%), accounting for a total of 80% (Blair and Schweit 2014).

Though the news media influenced the perception that the incidence of mass murder steadily increased from the 1960s to the 2000s, some reports suggested that this perception was based on distortion. Duwe (2005) evaluated FBI reports along with newspaper articles, network television stories, and magazine articles to suggest that the media's assertion at the time that mass murder was steadily on the rise was based on distortion. New data, however, suggest that there may indeed be a more recent trend of increased incidents. Although only 40% of the incidents in the 2014 FBI study described above met the federal definition of "mass killing," the data reflect a possible trend of increased incidents involving active shooters during the period studied. There were an average of 6.4 incidents per year in the initial 7 years studied and an average of 16.4 incidents per year in the next 7 years studied (Figure 62.1). It is unclear whether the same trend exists in incidents that would be strictly defined as mass murder.

A study of mass and school shootings occurring in the United States from 1998 to 2013 focused on whether temporal patterns indicated evidence of a contagion effect in

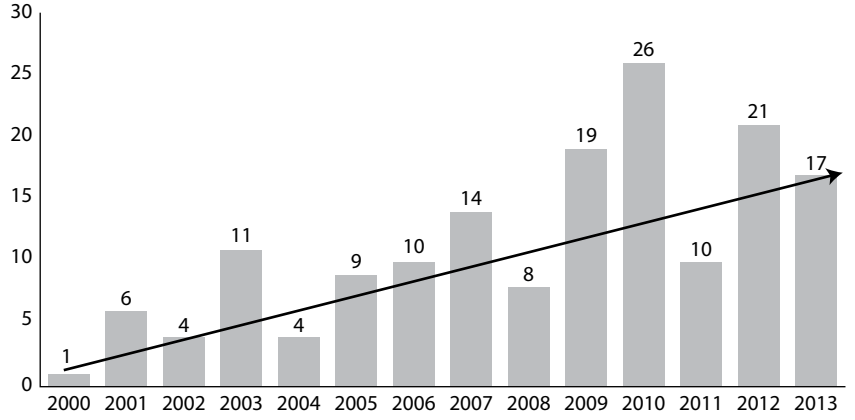

Figure 62.1 A study of 160 active shooter incidents in the United States between 2000 and 2013: Incidents annually. (From Blair JP and KW Schweit. 2014. *A Study of Active Shooter Incidents, 2000–2013*. Washington, DC: Texas State University and Federal Bureau of Investigation, U.S. Department of Justice.)

their immediate wake (Towers et al. 2015). The study suggested that mass shootings are incented by similar events in the immediate past, with a pattern of temporary increase in probability lasting 13 days. Mass shootings were found to occur, on average, approximately every 2 weeks, while school shootings occurred on average monthly. The authors suggested that certain individuals with inner mental turmoil might be inspired to act on previously suppressed urges by media exposure to mass shootings. No significant association was found between the rate of mass shootings and state prevalence of mental illness.

CLASSIFYING MASS MURDER

There is no exact profile of individuals who commit mass murder. However, studies looking into groups of mass murderers have produced a collection of commonalities. One detailed case study of five mass murderers found common traits and historical factors including the following: childhood bullying or isolation; turning into loners who felt socially isolated; demonstrating obsessional or rigid traits; being suspicious and holding grudges; externalization; narcissistic and grandiose personality traits; resentment; view of others being uncaring and rejecting; and fantasizing about violent revenge (Mullen 2004). Analysis of several individual mass murderers showed a common desire to leave a final message, typically through writings, audio recordings, photographs, and/or video recordings (Hempel et al. 1999; Knoll 2010). The contributing causes of mass murder events appear to involve a complex interplay of mental health issues, personality traits, and historical life events. Table 62.1 shows a biopsychosocial formulation of factors that may contribute to mass murder events.

There is not currently an established system for classifying mass murder. The literature contains vague descriptions of groups referred to as school shooters, disgruntled employees, pseudocommandos, and family annihilators. However, each group of mass murderer has characteristics that have been reported without tying them together into a usable system.

There is a classification system for evaluating the phenomenon of homicide–suicide (H-S), an incident involving one or more homicides followed by suicide, typically within a 24-hour period (Felthous and Hempel 1995; Bossarte et al. 2006). H-S events are typically well planned and differ from other forms of homicide. Fortunately, like mass murder, H-S is a rare event (Coid 1983; Bossarte et al. 2006).

One group proposed a classification system for H-S involving dual descriptions of the perpetrator's relationship to the victim(s) and the perpetrator's perceived

Table 62.1 Mass murder—contributing factors

Biological
- Psychosis
- Depression
- Brain pathology
- Personality disorders

Psychological
- Problems with self-esteem
- Persecutory/paranoid outlook
- Entitlement
- Antisocial traits
- Obsessional or rigid traits
- Narcissistic, grandiose traits
- Externalization—unable to take responsibility
- World seen as rejecting, uncaring
- Resentful with rumination on past humiliations
- Fantasize about violent revenge

Social
- Social alienation
- Being bullied
- Life stressors—marital, financial
- Access to and familiarity with firearms

motive (Marzuk et al. 1992). Of the five primary H-S types described by this group, estranged intimate partners (consortial–possessive type) account for 50%–75% of incidents. The other four types are consortial–physically ailing, filicide–suicide, familicide–suicide, and adversarial homicide (extrafamilial)–suicide (Marzuk et al. 1992).

The H-S classification system provides a useful model for classifying mass murder incidents because there is likely a similar thought process with the two events. The perpetrator typically goes into the attack expecting to die, either committing suicide or forcing the police to kill him or her (Mohandie and Meloy 2000). Based on these similarities to H-S, Knoll (2012) suggested a classification system for mass murder based on similar dual descriptions of the perpetrator's relationship to the victims (family, school, workplace, specific community, pseudocommunity, indiscriminate, etc.) and perceived motive (depressed, resentful, psychotic, etc.). The following are case examples involving common combinations.

Familial: Depressed type

Between December 22 and December 28, 1987, Ronald Gene Simmons orchestrated the single largest familial massacre in U.S. history. Simmons experienced financial, legal, and occupational problems in the years leading to the massacre. In 1981, he fled New Mexico while being investigated for allegedly fathering a child with his 17-year-old daughter. He later quit a job as an accounts receivable clerk after reports surfaced of inappropriate sexual advances. Months before the killing spree, Simmons instructed family members to dig a hole in the yard for a family outhouse. He subsequently placed his victims' bodies in the shallow pit.

Simmons began by killing his wife, granddaughter, and five of his children on December 22. Over nearly a week, he proceeded to kill 14 total family members and two other individuals. Simmons was sentenced to death in 1989 and executed in 1990, the quickest sentence-to-execution period since the death penalty was reinstated in 1976 (Swanlund 2015). Although Simmons never discussed his motivation for the murders, evidence suggests that he was angry with several family members. In a letter to his daughter, who he had allegedly impregnated, Simmons wrote, "You have destroyed me, and you have destroyed my trust in you … I will see you in Hell." He wrote the letter after she reported him for molesting her. Simmons' wife also tried to leave him repeatedly and was openly hostile toward him (Clark Prosecutor n.d.). The Simmons case shows a typical example of a frustrated, angry individual channeling his misery toward family members. Although the number of victims in this case was unusually large for the Familial–Depressed type, the motivation seems typical.

School: Resentful type

On December 14, 2012, 20-year-old Adam Lanza shot his 52-year-old mother Nancy Lanza in the head with a rifle as she lay in bed in their Newtown, Connecticut, home. He then drove to Sandy Hook Elementary where, armed with his mother's rifle, he blasted his way through the locked front entrance doors. He then initiated a rampage that took the lives of 20 children and six staff (Vigdor 2013). Lanza stalked the school's classrooms, shooting teachers and students as they hid unarmed. He shot all but two of his victims multiple times. Though accounts differ slightly, teachers and students alike reported that Lanza called to and cursed at his victims while pursuing them. The incident ended after only 5 minutes, with Lanza shooting himself in the head (Connecticut State Police 2013). Lanza completed the deadliest mass shooting at a grade school or high school and the second deadliest mass shooting by a single person in U.S. history, second only to Seung-Hui Cho at Virginia Tech in 2007 (Effron 2012).

Lanza's history sheds little light on the motivation behind the attack. He attended Sandy Hook Elementary briefly, but later left to be homeschooled. After getting his GED, he attended college for 2 years. According to his father, Lanza was diagnosed with a sensory-integration disorder during elementary school and later diagnosed with Asperger disorder and obsessive–compulsive disorder. He was briefly treated at Yale with behavioral therapy and citalopram (Schwarz and Ramilo 2014). Some items identified in Lanza's room suggested that he had an interest in mass murder, such as newspaper clippings about the attacks at Columbine High School and Northern Illinois University (Curry 2013). Family members recalled odd behaviors such as cutting off communication with his brother and father for 2 years before the shooting and only communicating with his mother by e-mail, despite living in the same home. A document detailing Lanza's perspective on women's inherent selfishness was identified after his death (Solomon 2014). However, investigators identified no documents specifically alluding to the attack at the school. Although most school shooters are actively enrolled in the school they target, this case stood out because it horrified the nation and brought school shootings and gun control to the forefront of the news.

Workplace: Resentful type

On November 5, 2009, Army psychiatrist Nidal Hasan staged the largest mass murder at a domestic U.S. military base in history. He opened fire with a semiautomatic weapon at the Fort Hood Soldier Readiness Processing Center, where soldiers were being assessed for deployment. Hasan arrived at the scene dressed in Islamic garb, bowed his head in prayer, and then screamed "Allahu Akbar [God is the greatest]" before firing on unarmed soldiers. Hasan represented himself at trial. During his opening statements, he openly confessed to committing the shootings and explained his jihadi motives. Reports surfaced that Hasan had been presenting as increasingly radical since 2005 and felt ambivalent about remaining in the U.S. Army due to the military killing Muslims (Weiss 2013). Hasan cited religious motivations for the shootings. Hasan referred to himself

as SoA, understood to represent shorthand for "Soldier of Allah." He wrote that there were irreconcilable differences between the belief systems of Islam and American democracy, and even renounced his U.S. citizenship (Herridge and Browne 2013). The Department of Defense officially classified the incident as "workplace violence" and did not mention terrorism in the report (Weiss 2013). Hasan was sentenced to death in August 2013 by a military court (Kenber 2013). Although this incident could also be classified as an act of terrorism, it is perhaps the most highly publicized workplace shooting in recent memory.

Specific community: Resentful type

On June 17, 2015, Dylann Roof opened fire at the Emanuel African Methodist Episcopal Church in Charleston, South Carolina. Roof spent about an hour at the church, participating in a prayer meeting, before starting the attack. He killed a total of nine victims. According to witnesses at the scene, Roof stood up and said he was there "to shoot black people" and made racially inflammatory statements to victims as he shot them. A friend of Roof indicated that he had alluded to a plan to "do something crazy" in hope of initiating a race riot (Sanchez and Payne 2015). Roof described himself as "awakened" by the situation involving Trayvon Martin, the African American teen who was shot and killed by George Zimmerman in 2012. On his personal website, Roof expressed frustration with the number of "black on white" crimes that he felt were not covered in the same detail by the media (The Last Rhodesian 2015). Roof posted a manifesto on his website (http://www.documentcloud.org/documents/2108059-lastrhodesian-manifesto.html) that summarized his racist stance and plan for an impending attack, as follows:

> I have no choice. I am not in the position to, alone, go into the ghetto and fight. I chose Charleston because it is [the] most historic city in my state, and at one time had the highest ratio of blacks to Whites [sic] in the country. We have no skinheads, no real KKK, no one doing anything but talking on the internet [sic]. Well someone has to have the bravery to take it to the real world, and I guess that has to be me.

Although the targets can differ, the unifying principle with the Specific Community–Resentful type is a group or groups that the perpetrator targets. In some cases, the act is racially based. In other cases, such as George Sodini, mass murderers of this type have targeted women based on the belief that they had been inappropriately rejected throughout their lifetime (Rubinkam 2009).

Pseudocommunity: Psychotic type

On April 3, 2009, Vietnamese immigrant Jiverly Wong burst into the Binghamton, New York, American Civic Association carrying two guns and wearing body armor. Wong had been taking English classes at the Civic Association. After blocking off the back exit using his father's car, Wong proceeded to kill 13 people before shooting himself. Although Wong's motivations initially seemed unclear, local police discovered that the incident was not entirely surprising to individuals close to him, including his father (Chief J. Zikuski, personal communication, April 4, 2009).

Soon after moving with his family from Vietnam to New York, Wong informed his father that somebody was trying to kill him. He stated, "They're in front of me and trying to capture me." Wong also complained of experiencing hallucinations involving people trying to harm him. He voluntarily went with his father to a hospital for treatment, but was released without being given treatment or a follow-up appointment. Wong's father later wondered whether their family's limited mastery of the English language contributed to his son not being treated (Huynh 2009).

After approximately 15 years in California, Wong returned to live with his parents in New York, at age 39. His family continued to notice concerning behaviors. For instance, Wong consistently wore long-sleeved shirts and pants, even during the heat of summer. He also behaved aggressively toward family members. He slapped his younger sister in the face and raised his voice toward his father over a minor household issue. Wong's father reported that in the weeks leading to the shooting, his son stopped eating, stopped watching television, and became increasingly isolative (Huynh 2009).

Witnesses at the scene indicated that Wong remained silent before opening fire. His motivation for the incident became more apparent after a local television station received a package from Wong, which included a two-page handwritten letter, photographs, and identification cards (Dowty 2009). The letter opens with the line, "I am Jiverly Wong Shooting [sic] the people" (Transcript of Letter 2009). He proceeded to explain that "undercover cop[s]" had been persecuting him for 18 years, which corresponded with the first time he discussed safety concerns with his father. In the letter, Wong described several classic paranoid ideas discussed by individuals with psychotic disorders. For instance, he mentioned "ultramodern" surveillance techniques employed by his persecutors. Upon returning to New York, Wong perceived the threats as more invasive and decided to take action. His fear and anger were driven primarily by his perceived interactions with a pseudocommunity of undercover law enforcement officers.

Indiscriminate: Resentful type

On July 18, 1984, James Huberty opened fire at a San Diego McDonald's, killing 21 (including five children) and injuring 19 others (Bosh 2014). He apparently chose the location based on familiarity with the restaurant (it was located only about 200 yards from his home) and his awareness that there were likely to be many people there. An angry,

nonpsychotic Huberty explained to his wife immediately before the incident that, "society had their chance" (Knoll 2012). On the way out of his house on the day of the incident, Huberty told his wife and daughter, "I'm going hunting for humans and I won't be back" (Bosh 2014). He gave no hint either before or after the incident that he had a grievance directed toward that particular McDonald's (Knoll 2012). The Indiscriminate–Resentful type of perpetrator typically experiences prolonged rage directed at society in general and releases it in an arbitrary public location.

PSEUDOCOMMANDO

Before Knoll (2012) proposed the classification system for mass murder described above, the bulk of the literature on mass murder had focused on a specific group of perpetrators. Dietz (1986) first coined the term "pseudocommando" to describe a group of mass murderers driven by anger, resentment, and general paranoia. This group is characteristically paranoid and develops anger and resentment toward groups of individuals or society in general. They tend to plan out the attack in advance, practice their actions, and show up armed with a heavy arsenal designed to maximize casualties. In the classification system proposed by Knoll (2012), the pseudocommando would most often be described as Specific Community–Resentful or Pseudocommunity–Psychotic, depending on whether their targets were based on reality or psychosis.

Mullen (2004) presented his findings based on personal evaluations of five pseudocommando mass murderers who were apprehended before being killed or killing themselves. As opposed to the common public perception that mass murderers suddenly "snap" before becoming violent, Mullen indicated that the events were instead well planned and rehearsed. The individuals appeared to be pursuing vengeance related to a personal agenda. They often arrived with a heavy arsenal, wore some form of "warrior" gear, and had a detailed plan. Both Dietz (1986) and Mullen (2004) described pseudocommandos as paranoid, preoccupied with firearms, and focused on a particular group (or society at large) for injustices in their lives.

Pseudocommando psychology

The tendency to desire revenge has been aptly described as "a ubiquitous response to narcissistic injury" (Lafarge 2006, 447). In most developed countries not actively involved in war, humans face less daily threats to physical survival than did ancestors thousands of years ago. As a result, narcissistic injuries that threaten self-esteem have moved more to the forefront. Narcissistic blows are therefore treated "as though they were a threat to our survival" (Menninger 2007, 123). The hard-wired threat response, often no longer needed for physical survival, remains available for excessive use when reacting to ego threats.

The pseudocommando seemingly becomes driven by the "fight response" when dealing with ego threats. Vulnerable individuals with fragile egos can develop a need to avenge their damaged egos. They begin recognizing a degree of honor in retaliating to perceived injustices they have collected over time (Dietz 1986). Menninger (2007) compared the response to a child who responds to pain by desiring others to recognize that they hurt and wanting others to experience similarly hurt.

Pseudocommandos typically share traits. Dietz noted that all men who had killed 10 or more victims in a single incident shared some element of paranoia (Dietz 1986). Pseudocommandos tend to experience a degree of envy, particularly directed at enjoyment experienced by others. In response, they look to destroy others' ability to enjoy possessions or social status (Hyatt-Williams 1998). They also have a sense of entitlement and adopt the mindset that their struggles are related to the actions of others rather than of their own creation (Knoll 2012). Related to the pseudocommando's fixed paranoia, they often eventually develop nihilism. Their feelings of hopelessness can then manifest into suicidal ideation and other self-defeating acts (Edwards and Holden 2001). Ultimately, pseudocommandos develop a heroic revenge fantasy and begin formulating an incident of mass murder as their final act in an unfair life.

SCHOOL SHOOTINGS: OVERVIEW

Recently, school shootings have received considerable media attention. A school shooting is generally defined as an individual discharging a firearm in an educational institution. While some school shootings are limited to a single victim, some fall under the category of "mass murder" or "spree killing," with multiple victims. Despite the media attention they receive, school shootings—in particular, mass school shootings—are a relatively rare event (Harding et al. 2002). Due to their rarity, there are no commonly accepted criteria for defining a school shooting, let alone a mass school shooting. Researchers have instead utilized pattern matching to analyze this phenomenon (Verlinden et al. 2000).

In response to the highly publicized Columbine shooting in Littleton, Colorado, in April 1999, the U.S. Department of Education and the U.S. Secret Service launched the Safe School Initiative, an extensive examination of "targeted violence" in U.S. schools between 1974 and 2000 (Vossekuil et al. 2004). In the study, an incident of "targeted school violence" was defined as "any incident where (i) a current student or recent former student attacked someone at his or her school with lethal means (e.g., a gun or knife); and (ii) where the student attacker purposefully chose his or her school as the location of the attack" (Vossekuil et al. 2004, 7). The researchers identified 37 episodes of targeted school violence involving 41 attackers during the study period. In 73% of cases, the attacker(s) killed one or more students, faculty, or other individuals at the school; in 24% of cases, the attacker(s) used a weapon to injure at least one person at school; in the remaining case, a student killed his family before holding his class hostage. Regarding timing, 59% of cases occurred

during the school day, 22% occurred prior to school, and 16% occurred after school. Ninety-five percent of the attackers were current students at the school, while 5% were former students. In the majority of incidents (81%), the attacker acted alone. Less commonly, there was a single attacker who received assistance in planning the attack (11%) or multiple attackers who acted together (8%).

Preti (2008) gathered data from Wikipedia to evaluate school shootings that occurred around the world between 1966 and 2008. He identified a total of 63 episodes of school shooting, 44 of which occurred in the United States, 7 in Canada, 7 in Europe, and 5 elsewhere. The United States had the greatest number of school shootings per year (1 per year), with a robust trend toward increasing episodes over time. Regarding timing, 24 of the documented events occurred between May 1999 and 2008, whereas 20 occurred between 1966 and April 1999. The number of individuals killed in the shootings ranged from 0 to 33; the number wounded ranged from 0 to 37. Preti noted that often a single perpetrator was responsible for the shooting and that it was more common for the shooting to end in suicide in Europe than in the United States, whereas more U.S. cases resulted in capture.

School shooters and their victims

Violence risk assessment is particularly challenging for rare events like school shootings (Mulvey and Cauffman 2001). Due to the infrequency and heterogeneity of school shootings, there is not currently a reliable profile for potential school shooters (Reddy et al. 2001). In the Safe School Initiative (SSI) report, all 41 identified attackers were males between the ages of 11 and 21, with 85% between the ages of 13 and 18 at the time of the attack. Social isolation and peer rejection have been associated with most incidents of school shooting in the United States (Band and Harpold 1999; Leary et al. 2003). Table 62.2 lists characteristics commonly associated with school shootings.

The SSI report provided additional pertinent demographic data. Seventy-six percent of attackers were Caucasian, 12% were African American, 5% were Hispanic, and the remaining three were Native Alaskan, Native American, and Asian. In terms of family background, the majority (63%) came from two-parent homes, either with two biological parents (44%) or one biological parent and one stepparent (19%). Attackers' school performance varied considerably, with grades ranging from excellent to failing, though many (41%) were receiving As and Bs. Attackers had varied social relationships, ranging from socially isolated to popular among "mainstream students." The majority (63%) had experienced no or rare disciplinary action.

The SSI authors found that most (71%) of the attackers had felt bullied, persecuted, or injured by others prior to the attack. Though less than one-fifth of attackers had previously received a mental health diagnosis, the majority (78%) had a history of suicide attempts or suicidal thoughts. The majority of attackers (98%) had experienced a major loss before the incident, including a perceived failure or loss of status (66%), the loss of a loved one or a significant relationship (51%), and/or a major illness experienced by the attacker or someone close to them (15%). Most individuals demonstrated difficulty coping with the loss (83%).

Table 62.2 School shootings—contributing factors

Individual
- Threatens violence
- Has detailed plan
- Blames others for problems
- History of aggression
- Uncontrolled anger

Family Factors
- Lack of supervision
- Troubled family relationships

School/Peer Factors
- Poor coping and social skills
- Feels rejected by peers
- Feels picked on and persecuted
- Socially isolated

Social/Environmental Factors
- Access to firearms
- Fascination with weapons/explosives
- Preoccupation with violent media/music

Attack-Related Behaviors
- Interest in targeted violence and weapons
- Organized for attack
- Communicated violent intentions
- Lacks prosocial supports

Source: Verlinden S, M Hersen, and J Thomas. 2000. *Clinical Psychology Review* 20(1):3–56. With permission.

Evidence from the SSI indicated that most school shootings are not impulsive, but rather are coordinated attacks. The attacker targeted at least one school administrator, teacher, or staff member in over half of the events (54%). The attacker targeted students in slightly fewer (41%). In the majority of incidents (73%), attackers had a grievance against at least one target prior to the event. The intended target became a victim in 46% of the attacks. Of nontargeted individuals injured or killed in the attacks, 57% were students and 39% were administrators, teachers, or staff.

Aftermath of school shootings

School shootings have deep emotional and political impacts on communities. Violent events in educational settings raise important questions involving gun control, school safety, bullying, and violent media. Following the Newtown attack, there was a flurry of gun control legislation. New York passed the Secure Ammunition and Firearms Enforcement (SAFE) Act of 2013; other states, such as Connecticut and Maryland, increased their firearms restrictions (Jackson 2013; Press 2013; Seiler 2013). The Assault Weapons Ban of

2013 was introduced to Congress, but defeated in the Senate (Weisman 2013).

Gun control laws focusing broadly on mental illness have been criticized as reactionary and unlikely to have an impact on preventing mass shootings or preventing firearm deaths (Appelbaum and Swanson 2010; Swanson 2013). Concurrently, concern has been expressed that such laws may overidentify persons as being at risk (false-positive identifications), as well as dissuade individuals from seeking needed treatment or making critical therapy disclosures (Swanson 2013).

THREAT ASSESSMENT

Over time, the mental health system has adopted a role with mass murder. Mental health professionals, particularly those with forensic training, are often asked to perform violence risk assessments. Fingers are also frequently pointed at the mental health system after mass murder incidents, whether the perpetrator was engaged in mental health treatment at the time or not (Firger 2014).

For over 50 years, the field of violence risk assessment has continued to grow. One of the important developments has involved the creation of structured violence risk assessment instruments (e.g., Historical Clinical Risk Management-20 [HCR-20], Violence Risk Appraisal Guide [VRAG], Classification of Violence Risk [COVR]) and the data that have derived from them (Monahan 2008). Mental health providers have historically been accused of overpredicting violence. In the case of mass murder, predicting relatively rare—though extremely tragic—events is a challenging endeavor.

Threat assessment on school and college campuses is a relatively new and rapidly evolving field. Expert consensus recommends a multidisciplinary threat assessment and management team whose priorities include a shared mission, regular communication, and networking (Hoffman and Zamboni 2014). Despite recent attention to threat management in school settings, establishing a rapport with school administrators about the need for collaboration and threat assessment teams remains a barrier.

Warning behaviors concerning for impending incidents of mass murder have begun to be described in the literature (Meloy et al. 2012). One group utilized existing research on targeted violence, experience with previous cases, and discussions with colleagues to propose eight warning behaviors to consider when conducting threat assessments (Meloy et al. 2012; Meloy et al. 2014). Those behaviors include behaviors suggesting planning, behaviors suggesting preoccupation, identification warning behaviors, novel aggression warning behavior, energy burst warning behavior, communication to a third party, increasing desperation or distress, and directly communicated threats. Meloy (2015) later published an article focused on the role of identification in threat assessment. Additional research will be essential in the continued effort to improve mental health professionals' threat assessments.

SUMMARY KEY POINTS

- Mass shootings are highly tragic, though extremely rare. Approximately six events on average occur per year.
- The majority of shootings occur in a place of business or an educational environment.
- A single individual who has planned and prepared for the incident carries out most shootings.
- Experience and research suggest that focusing media responsibility and encouraging third parties to report warning behaviors or leaked intent have the most potential for prevention.
- Policies and laws focusing on dangerous behaviors, as opposed to psychiatric diagnoses, are more likely to have a preventive effect.

Terrorism

WILLIAM H. REID, DANIEL J. REID, AND CHRIS E. STOUT

INTRODUCTION

This chapter will address several kinds of terror–violence and other acts that purposely create injury or fear in noncombatants. Not all terrorizing activity is physically violent. Although some discussions focus on transnational terrorism, we include activity that targets other large groups (such as religious believers or socioeconomic groups), private industry (e.g., large retailers, energy companies, and agricultural conglomerates), smaller civilian groups (communities, schools, public facilities, and gatherings), and cyber-communities. We include "cyberterrorism" and acts that, although not directly violent, nevertheless create damage or instill fear by virtue of widespread communication by perpetrators, other individuals, social media, or news media (Duarte et al. 2011; Peleg and Mass-Friedman 2013).

We generally separate "terrorism" topics from conventional criminal acts, acts of war, and victims of conventional crime or warfare, although the concepts overlap. Acts of war figure more prominently when addressing victims and victim care, although victims of terrorist acts often receive different (or combined) kinds of injuries, react differently in some ways, and should sometimes be treated differently, than most victims of war (Peleg et al. 2010; Miller 2011).

One's personal views affect whether or not one defines many acts as "terrorism." Professor J.K. Zawodny, a Polish underground combatant during World War II, wrote, "(O)ne man's terrorist is another man's freedom fighter" (JK Zawodny, personal communication, 1985). It is sometimes hard to tell whether a bombing is a political act or "senseless violence," or whether a military or police action meets common criteria for terrorism. Many would say that such distinctions matter little in the long run, especially to the victims.

Some have spoken of poverty or political repression as a fertile garden for the development of terrorism. It is now clear that poverty *per se* is not associated with increased violence, terrorism, or the "radicalization" of social protest. Some authors have noted that societies that move toward violence are very often those that are improving socioeconomically; internal group or terroristic violence routinely suggests a self-destructive societal trend (JK Zawodny personal communication, 1985; Alderdice 2009).

The U.S. Bureau of Counterterrorism has maintained a list of Foreign Terrorist Organizations (FTOs) since 1997. The list began with 20 large and small groups, including the Abu Nidal Organization, HAMAS, *Hezbollah* (*Hizballah*), Shining Path, and others, largely based in the Middle East, Asia, and South America. The "official" list grew slowly for a few years, starting with the addition of *al-Qa'ida* (*al-Qaeda*) in late 1999. By September 2012, the number had climbed to 57, with 34 added since September 11, 2001. Groups added after September 2001 are almost all associated with the Middle East and North Africa. Only six have been removed from the list since 2001 (Bureau of Counterterrorism 2015). It is a criminal offense for U.S. citizens or persons within U.S. jurisdictions to knowingly provide material support or resources to an FTO (U.S. Department of State 2000).

Truly valid and reliable studies of terrorism, its victims, and population responses to terrorism risk and events are difficult to separate from relatively useless surveys, anecdotes, and editorials, but there is a well-informed post-disaster and victim intervention literature. Many of the references herein derive from Israel, England, and the United States, with U.S. studies often focusing on the September 11, 2001, attacks and the April 19, 1995, bombing of the Alfred P. Murrah Federal Building in Oklahoma City.

TERRORISTS AND TERRORISM

Hacker, largely known for his work on skyjackings, differentiated terrorists into overlapping groups of "criminals, crusaders, and crazies" (Hacker 1977). *Criminal* activities were those based primarily on personal gain. *Crusading* referred to terrorism that attempts to support social or political causes. *Crazies* referred to perpetrators whose violence or extortion arises from highly personalized, often delusional, roots. Hacker's classification, with a few *caveats*, is still useful, and helps define some of the roles psychiatrists and other mental health professionals should attempt or avoid.

Post (2007) offered a more recent categorization of national and transnational terrorism. *National separatists* (such as the Irish Republican Army or Abu Nidal) are often the latest generation of a continuum. Idealistic or anarchist *social revolutionaries* tend to be youth and young adults rebelling against a status quo and clamoring for some version of what they purport to be social justice (cf. the Red Brigades, Shining Path, and the Revolutionary Armed Forces of Colombia [FARC]). For some, violence itself, irrespective of cause, effect, or consequence, seems to be a liberating or cleansing influence. *Religious extremists*, currently represented by many Middle Eastern groups (such as the Taliban and *al-Qa'ida*, which have existed for decades, and the relatively newer Islamic State) have become much more potent internationally over recent decades.

The terrorist's true purpose and avowed purpose are often different, but usually overlap. Activity purported to be altruistic may come from delusional roots or criminal intent. Criminal activity may generate money and other resources for some political or quasi-political goal. Embittered, distraught, or simply youthful rebels are often manipulated by experienced agitators to create media events and suggest much larger numbers than truly exist. Actions "for the people" may be based in revenge, narcissism, or merely love of violence or chaos. When terrorism represents legitimate protest, some faction of the protestors has often become radicalized and moved along a "developmental continuum" between social activism and terrorism (Reshetnikov 2008).

There is no single agreed-upon classification system for terrorism or terrorists. However, several systems have been proposed by previous authors, as summarized in Table 63.1. Reid and colleagues (2015) recently incorporated the concept of cyberterrorism into their classification system.

Cyberterrorism includes Internet-mediated damage to economic and monetary systems, finance mechanisms (such as credit card payment systems), communication systems, recordkeeping systems, power grids, and public confidence in all of those. Its effect on U.S. targets and/or people has become much greater during the past decade. Its sources may lie anywhere in the world, with large groups or single hackers. Very small groups can wreak substantial damage and, sometimes, give the impression that they are much larger (or represent more people than they actually do). The consequences can be more destructive than those of traditionally defined terrorist organizations.

Table 63.1 Examples of terrorist/terrorism classifications

Hacker (1977)	"Criminals, Crusaders, and Crazies"
Trioni, general (1999)	Criminal, Irrational, Political, State, Religious, Ethnic/Cultural/Tribal
Trioni, state related (1999)	Resistance to Colonial Rule, Separatist, Internal-Political (to control a state or system), Anarchistic–Ideological (to destroy a state system), Support for External Takeover
Post (2007)	National Separatist, Social Revolutionary, Religious Extremist
Reid et al. (2015)	Wholly Domestic Violent, Violent from Foreign Sources, Cyberterrorism (foreign or domestic)

The overall success of a terrorist act is measured by its effect on the larger population. The act may preoccupy a government or large number of people and provoke substantial social response. Terrorism is thus useful to its perpetrators in many ways, including publicity, instilling fear, displaying power, demonstrating target weakness, manipulating governments and citizens, exacting revenge, effecting direct social damage such as economic collapse, and increasing repression (either directly or through government reaction).

EXTENT OF THE PROBLEM

The ancient adage "kill one, scare 10,000" still works and makes it easy to influence or control people with little expenditure by the terrorist. Much ongoing concern—as contrasted with "perceived" threat—comes from the availability, portability, affordability, and "import-ability" of nuclear and biochemical weapons, infrastructure vulnerability, and ubiquitous sensationalism by both news and social media.

The secondary and tertiary "scare" value (beyond physical damage and effects on specific targets) of real threats is enhanced exponentially by the speed and breadth of media coverage. Blends of factual reporting and editorializing, publicity on biased public media such as *Al-Jazeera* and many state-sponsored outlets, and the availability of social networks such as Facebook, Twitter, Instagram, *Weibo*, and *VKontakte* routinely expand and distort news.

Until the events of September 11, 2001, the great majority of U.S. civilians considered themselves insulated from transnational terrorism. Nevertheless, Americans in foreign countries have sometimes been part of a larger U.S. target (e.g., the 2012 bombing of the U.S. diplomatic mission in Benghazi, Libya; the 2000 bombing of the *USS Cole* in Yemen). Others may be caught coincidentally in non-U.S. targets (e.g., in the 2008 Mumbai bombings by *mujahedeen*, in which Americans and Britons were coincidentally present but singled out for additional violence [Sengupta 2008]).

Despite the relatively small number of directly injured Americans, terrorism has had a substantial effect on way of life in the United States. Millions of Americans and others worldwide who have not experienced physical injury are nonetheless affected by uninvited political change and abridgement of freedoms. In the United States, laws, rules and expectations about travel, food safety, communication, gatherings, and basic privacy have markedly changed daily routines. Huge portions of the U.S. population have become inured to those abridgements and inconveniences; entire generations now assume that searches and scans at airports, ever more tamper-resistant food and product packaging, government surveillance of mail and electronic communications, heavily armed police at public events, "hardening"

strategically unimportant buildings to withstand attack, and closing off entire streets in front of government buildings and public monuments are "normal."

COPING WITH THE THREAT

Public perception of risk

With certain exceptions, *perceived* personal risk from terrorist threat tends to be higher—sometimes much higher—than actual risk, particularly in the United States. That perception extends from the generic to specific kinds of events, such as biological or radiological terrorism (Pearce et al. 2013). Public emotional and behavioral response to the 2001 attacks in New York and Washington, DC, had waned substantially a year after the events, but cognitive effects remained many years later (McArdle et al. 2012). Within a year of the 9/11 events, one of the authors (WHR) informally queried a number of psychiatrists practicing in Manhattan and the District of Columbia about their perceptions of continuing terrorism risk and their thoughts about remaining in those areas. Every person asked said that he or she believed the risk of another incident was high, but none planned to relocate.

There is evidence that both time without an event and constant threat itself are associated with lowered public concern. Israeli residents are very well studied in this regard. The effects of living in an industrialized (i.e., not "third-world") environment which is *per se* dangerous are significant to be sure, but one often sees a sort of community resilience and habituation to the constant risk of attack. Education and psychological-response-mitigation programs have been effective (cf. Farchi and Gidron 2010; Berger et al. 2012). Interestingly, the broad economic effects of risk from terrorism or war appear to be less than one might expect (Peleg et al. 2011).

One Australian study found a significant decrease in expressed public concern between 2007 and 2010, in spite of that country's proximity to volatile environments in Southeast Asia and Micronesia (Stevens et al. 2011). While a larger portion of Australians believe that the national threat of terrorism remains high and accept the possibility of future precautions, concern about being personally affected appears to have moderated over time. Subgroups of poorly educated people and migrants continued to be "disproportionately concerned."

One political consequence of external threat and perception of risk is increased public acceptance of authoritarianism (Asbrock and Fritsche 2013). People who are frightened, confused, or ambivalent generally welcome direction and are often indifferent to its source or potential consequences beyond their immediate security.

Role of the Internet and Web-based media

Separate from the important concept of cyberterrorism, the Internet and its contributions to rapid, uncensored, and unfiltered mass communication has increased both terrorism and its effects on large populations. Media accessibility in general, and Web-based media in particular, have made it easier and more efficient to develop and communicate within groups, including those associated with terror–violence. Some writers refer to "virtual communities of hatred" that contribute greatly to the radicalizing of people who otherwise would not actually participate in terrorism (Post 2010).

Terrorist "psychology"

It is a mistake to search for a single personality type or uniform "terrorist mindset," particularly without defining a specific kind of activity. There are many kinds of terrorist behaviors and motivations. Most terrorists do not demonstrate serious psychopathology, although (limiting our comments to organized, quasi-political groups and eliminating frankly psychotic, simply criminal, and/or revenge-motivated perpetrators) people with certain personality traits and tendencies are disproportionally drawn to terrorist roles.

Most of those traits are so generic that they are of limited utility for early prediction of terror–violence, but it may be helpful to monitor known suspects or groups for conditions that are correlated with destructive action. Those who are action oriented, aggressive, stimulus hungry, excitement seeking, and externalizing are statistically associated with a greater likelihood of overt action.

Other kinds of people often support terrorist group efforts, making eventual action possible but not participating directly in it. The personality traits most often seen are antisocial (including the truly psychopathic), narcissistic, borderline, and paranoid. That correlation can be established once the group is defined or terroristic behavior has taken place, but it is fruitless (and unfair) to surmise in the other direction (i.e., to try to predict terroristic behavior based on personality type).

The Japanese FTO United Red Army stated years ago that, "We intend to recruit young people who have lost hope in living, and their families, as well as in society. We want their explosive energy." One analysis of their known members indicated that 25% had lost one or both parents by the age of 14, with the loss of one's father being most disruptive. Of those whose parents were still living, 79% reported severe conflict with them. Over 33% had prior juvenile court convictions (Trioni 1999).

Members of FTOs—as contrasted with their leaders—often submerge their own identities into that of the group. Most organizations have little tolerance for differences of opinion about goals and actions. In addition, the group must commit terroristic acts to justify its existence. This group dynamic can press for the perpetuation, and often escalation, of violence.

There is a limited literature that describes the process of converting victims of war or terrorism into instruments of violence for terrorist leaders. Post (2000), discussing

generational transmission of nationalist–separatist hatred and revenge, describes a former Palestinian refugee recruited by Abu Nidal to participate in bombing an Egyptian airliner.

Decades ago, Janis (1972) applied the old theory of "groupthink" to terrorist organizations. Not being caught, or being quickly released—such as through public outcry (cf. groups that press for release of *al-Qa'ida* combatants from U.S. detention facilities), extortion, or prisoner trades—can lead group members to illusions of invulnerability, which leads in turn to unreasonable optimism and terrorist risk taking. False presumptions of group "morality" are often added to propaganda and one-dimensional perceptions of the terrorist's "enemy" as evil, which subsidizes the perspective that violent behavior, even against innocent victims, is justified.

VICTIMS AND VICTIM RECOVERY

Work with victims is by far the largest terrorism-related role for mental health professionals. Much of the necessary skill and many of the syndromes encountered, such as anxiety, depression, and acute- and post-traumatic stress disorder, are already part of most clinicians' experience. Other situations require special training and sensitivity (such as working with teachers and students after attacks, child-victims, mass casualty situations, military personnel or civilians in danger zones chronically exposed to the threat of sudden violence, torture victims, first responders, and people preparing to travel or deploy to dangerous environments).

Individual victims

Victim response to terror–violence is not random. Understanding response patterns makes care more effective. Military and intelligence community professionals see value in incorporating critical incident debriefing and experienced mental health consultation when faced with terrorist acts, and integrating them into comprehensive counterterrorist programs (Applewhite and Dickins 1997). In the authors' experience, however, immediate "debriefing" (in the sense of intense questioning) is countertherapeutic and interferes with recovery. In dangerous situations, information may be a top priority, but victims fare better when simply provided unconditional support as they deal with trauma.

Victims of very recent violence require special understanding. A gentle approach, offering basic help such as food and a soft word, is the best place to start. Rapid-fire questioning, as frequently seen in movies or on television, should be avoided. Therapeutic actions that depend on the therapist's identifying with the victim are often ill advised. In mass casualties, efforts should be coordinated, which involves cooperating with local agencies and laying groundwork for lasting support.

The care of hostage victims and persons who have been tortured is particularly specialized. The authors strongly recommend special study and/or supervision for those working with such individuals, whether the trauma is recent or in the distant past (e.g., Holocaust survivors). Civilians who experience chronic anticipation of attack (such as many children in Israeli schools and *kibbutzim*, Nigerians living in fear of *Fulani* Muslim radicals, community victims of Mexican and South American drug wars, and many refugees) are also complex, especially when the terror is perceived—rightly or wrongly—as perpetrated by the State itself (Palmieri et al. 2010; Berger et al. 2012).

There is an expected correlation between severity of exposure to violent events and the extent and duration of posttraumatic symptoms (Desivilya et al. 1996; Henriksen et al. 2010; Scrimin et al. 2011). However, intensity of the trauma is not always directly related to the intensity and duration of its effects; severe trauma does not necessarily portend severe psychological symptoms. Tuchner et al. (2010) found no significant correlation between injury severity and quality of life for terrorist attack survivors after 2 years. Razik et al. (2013) found a similar lack of correlation in Pakistani emergency responders. Victims react differently to various combinations of trauma severity, chronicity, and type.

Expecting recovery is associated with *actual* recovery. Most victims have fairly good emotional recovery from terrorism-related sudden physical injury (North et al. 2011). Those who are chronically viewed as "victims" by family, associates, lawyers, and courts tend to respond less well to treatment, and sometimes deteriorate unnecessarily over time. This is consistent with older studies indicating that the majority of victims of ordinary disasters recover without long-lasting, substantial posttraumatic effects (Ursano et al. 1995), and that media exposure and personal injury litigation can exaggerate perceived symptoms and claims of distress.

PSYCHIATRIC PATIENTS

People with pre-existing serious psychiatric illness, as a group, develop proportionately worse acute and chronic posttraumatic symptoms than controls. Effects vary by individual and diagnostic category, and the syndromes seen are often not the same as subjective complaints (Franz et al., 2009). Caregivers should be alert for subtle presentations.

EMERGENCY RESPONDERS

A number of studies point out that emergency responders are emotionally vulnerable to repetitive exposure to tragedy, which is often mixed with immediate danger to themselves (Misra et al. 2009; Strand et al. 2010). In Pakistan, approximately 80% of first responders have been exposed to terrorist attacks, with prevalence rates of posttraumatic stress disorder (PTSD) and similar syndromes in the "high range" for similar workers in the West (Razik et al. 2013).

Modern Western first-responder teams often have sophisticated mental health support systems, including mandatory evaluations and offers of counseling. Nevertheless, a number of factors—including professional stigma, "macho" self-image, peer pressure, and perception of career blemishes—may interfere with individuals' use of available services.

Qualified post-shooting counseling for law enforcement officers, and other forms of intervention by experienced professionals, is sometimes as simple as good stress management. Military interventions are often most effective when provided in the field or near the current campaign, where they can occur without delay and in mission-relevant settings. One approach for military personnel returning from combat suggests returning them home by sea rather than by air, allowing for counseling to begin in transit and creating a gradual transition (Johnston and Dipp 2009).

SUICIDE AFTER TERRORIST EVENTS

The available studies, primarily of Western events and particularly the U.S. 9/11 attack and Oklahoma City bombings, indicate no general increase in suicide rates in either direct victims (including those with physical disabilities) or victimized regional societies (Pridemore et al. 2009; Weizman et al. 2009; Claassen et al. 2010). The Weizman (2009) study found some increase during one 11-month segment (December 2000 to October 2001) of a 6-year period.

Victims' families

Families of victims are victims as well (Dreman and Cohen 1990; Martin-Peña et al. 2011). Release of hostages who have been held for months or years brings a new and unexpected set of problems to the family, including guilt about some feelings and behaviors while the victim was away, disruption of the family equilibrium established in the victim's absence, and denial of the many issues that must be faced once release is secured. Divorce is extremely common after a hostage–spouse returns. The offspring of victims of war and concentration camps, including Holocaust victims, bear stigmata that may or may not be seen as symptoms (Dreman 1989).

Military families have been particularly well studied. Research on U.S. military deployments, especially to Iraq and Afghanistan, in which the concept of "terrorism" figures more prominently than in past campaigns, reflects the armed forces' progress in recognizing family reactions and needs. Military families generally tolerate deployments well. Most families restabilize without incident after the deployed person's return (Faber et al. 2008).

Community and societal victims

Large segments of the population who are not physically touched by terror–violence nonetheless bear peripheral effects (Reid 1989). Fears of airplane hijacking or bombing, travel restrictions, worry about privacy, eroded faith in financial institutions, bias against entire countries and cultures, and the like contribute to a general feeling that the world is dangerous.

The phrase *community resilience* is commonly used to describe good societal functioning (Butler et al. 2009; Ahmed et al. 2011; Ferrando et al. 2011; Johnson and Luna 2011). In spite of measurable—often inconvenient or repressive—social changes in response to terrorist threats, diagnosable psychopathology attributable to terrorism is not the rule in communities that are not under direct attack. Business tends to return quickly to normal or near normal. Relatively few people move away (unless the risk is very high). High-profile persons, such as politicians targeted for assassination, generally tolerate risk, employ security measures, and carry on (Nijdam et al. 2010).

Some community subgroups are more adversely affected. They include, depending on circumstances, migrant populations, those with less education, Holocaust survivors, persons with less effective prior functioning, women, persons with higher tested levels of neuroticism, those with lower tested extroversion, and those with "negative worldview changes" (Butler et al. 2009; Ahmed et al. 2011; Shmotkin and Keinan 2011; Stevens et al. 2011; Amital et al. 2012). Subgroups with relatively better outcomes tend to be those with the opposite characteristics.

Strong religious identification, regardless of culture or denomination, appears to provide substantial protection against the emotional effects of terrorism (Levav et al. 2008; Ahmed et al. 2011; Korn and Zukerman 2011). "Spirituality" has protective value as well, but should be considered separately from "religiosity" (McIntosh et al. 2011).

OTHER ROLES FOR MENTAL HEALTH PROFESSIONALS

Law enforcement training and support

Qualified mental health professionals can offer basic clinical training to law enforcement and military response teams that may be useful in crisis intervention, assessment of perpetrators and victims, victim support, stress management, department risk management, and a number of other areas. This does not mean clinicians should become field interveners or negotiators, or that police officers will acquire the skills and experience of clinicians. Experienced law enforcement, first responder, and military professionals routinely possess considerable intuition and psychological skill, but one should not mistake bravado or "street smarts" for deeper knowledge.

Some professional "profiling" teams, such as those trained and maintained by the FBI and a few private groups, have limited success in identifying perpetrators and assessing and predicting criminal behavior. The best profilers are typically experienced law enforcement specialists, not mental health professionals. Deducing perpetrator mindsets and predicting behavior based on limited information are primarily the stuff of fiction.

The issue of "agency" is very important when working with police or the military. Therapists who work within law enforcement and military organizations must be familiar with—and accept—their particular rules and expectations. It is easy to find oneself in an unethical position, or at least sliding down a "slippery slope."

PERPETRATOR EVALUATION AND TREATMENT

The few subspecialty-trained clinical professionals who deal with perpetrators, particularly in "field" situations of impending danger (such as unfolding terrorist activity), interrogation (military or civilian), or post-arrest evaluation should understand completely the broad implications of their activities. These include, but may not be limited to, what may happen to the perpetrator as a result of the clinician's involvement, ethical implications of such involvement, and effects on the clinician's own psyche and career. One should be aware of the uses to which evaluation findings may be put, and notify the evaluee (as appropriate to the situation and ethically required with law enforcement defendants) of one's intent, constraints on confidentiality, and the like. If the person has recently been arrested, the clinician should verify that defense counsel has been retained and the evaluee's rights as a criminal defendant have been appropriately protected.

Like other detainees, accused terrorists sometimes require psychiatric treatment in jails or prisons. Treatment of ill or injured perpetrators is a matter of clinical skill and clinical ethics. There is a small literature on the legal and bioethical dilemmas associated with treating terrorists, separate from the common roles of correctional physician or therapist (see e.g., Gesundheit et al. 2009).

Cases involving terrorism are often sensationalized. Evaluators should take pains to work professionally and to use appropriate forensic procedures, being careful not to step outside the bounds of their expertise and ethics.

Roles to avoid

Many clinicians legitimately participate in military, law enforcement, and civilian intelligence operations, but psychiatrists and psychologists are rarely trained combatants or law enforcement officers. Their roles must be clear and within carefully developed training and ethics guidelines. This is not merely a weighing of one ethic against another (such as confidentiality against danger), or of replacing traditional ethics with situational ones. If, for example, a police or military commander asks a psychiatrist about surreptitiously placing a drug in a hostage-taker's food to sedate him, that doctor (almost certainly inexperienced in hostage negotiation, lacking complete information about the situation, and acting in the heat of the moment) should not participate, even if tempted by a so-called "greater good" of protecting hostages. The "greater good" may or may not be truly greater, and the action may or may not really protect hostages. The only certainties are the immediate ethical breach and the slippery slope on which the professional will find himself or herself.

"Role confusion" is another reason to separate law enforcement from clinical activity. Consider the following example from the authors' experience:

Dr. A, a psychiatrist, introduced himself to one of the authors. He said, with some *braggadocio*, that he was a "member of the (city) SWAT (Special Weapons and Tactics) team," participated in anti-terrorism scenarios and drills, and was carrying a concealed handgun (implying that he had to be prepared for dangerous duty at all times). It soon became clear that he had been a police consultant and liked to view himself as part of the terror–violence and hostage response team. A local law enforcement executive later revealed that the clinician was not authorized to carry the weapon (that state had no concealed-carry permit statute at the time) and was considered something of a "kook" by area cops.

SUMMARY

Terrorism is a complex topic that, contrary to some published papers and many media stories, supports few absolutes and defies "unified" theories of cause or cure. Psychiatry and other mental health professions are irrelevant to many of its facets, but there are clinical and forensic roles for qualified clinicians.

SUMMARY KEY POINTS

- Terrorism has existed since social leaders—especially those of out-of-power groups—discovered the maxim "Kill one, scare 10,000." Broad perpetrator descriptions include Hacker's "criminals, crusaders and crazies" (1977), as well as more specific categories that recognize particular purposes in national and transnational groups, sometimes including internal revolutionaries and "freedom fighters."
- Despite the relatively small number of directly injured U.S. citizens, damage to Americans' way of life from terrorism has been substantial. Nonphysical damage in the United States and internationally includes general anxiety about safety, government or self-imposed restrictions, abridgement of freedoms, eroded faith in social and financial institutions, and overly broad bias against countries and cultures associated with terrorism.
- With certain exceptions, the public's *perceived* personal risk from terrorist threat tends to be much higher than *actual* risk, particularly in the United States.
- The Internet and rapid, uncensored, and unfiltered mass communication has had an enormous

role in the propagation of, and increased effects of, terrorism.
- Most terrorists do not demonstrate serious psychopathology. It is a mistake to search for one or two personality types or a uniform "terrorist mindset."
- Work with victims is by far the largest role for mental health professionals in the general field of terrorism. Victim response to terror–violence is not random; there are patterns that suggest avenues of effective care.
- Mental health professionals must avoid role confusion. Victim services, law enforcement training and support, and perpetrator evaluation and treatment are our most appropriate tasks.

KANG CHOI AND MOHAN NAIR

INTRODUCTION

Stalking has remained firmly fixed in the public eye. High-profile cases create the belief that erotomanic stalkers bent on murdering celebrities are the typical situation, despite evidence to the contrary. For a number of reasons, stalking has received increased attention and investigation over recent years. This chapter presents an overview of what has been learned about traditional, physical stalking.

Stalking has continued to be a significant forensic topic since the first stalking law was established in California in 1990. Stalking is defined as a pattern of intentional, unwanted, repeated behaviors directed at a person that cause fear or that would cause a reasonable person to feel fear (Spitzberg and Cupach 2007). Prior to 1990, the term *stalking* was primarily associated with psychiatric conditions considered relatively rare (e.g., erotomania and delusional disorders) and often involved celebrities and public figures. However, stalking arising from dysfunctional courtship behaviors and domestic conflict has now become the dominant focus. Research has shown consistently that most stalking situations arise out of ex-intimate situations. Ex-intimate stalkers are also the most violent. In contrast, stalkers of public figures and celebrities are among the least violent (Meloy et al. 2008).

Following the 1989 murder of actress Rebecca Schaeffer by an enraged, obsessed fan, and the killing of four Orange County women by ex-intimates, California became the first state to enact an anti-stalking law. The media's portrayal of stalking-related violence in conjunction with the efforts of domestic violence prevention advocates forced rapid (and in the opinion of some, hasty) legislation that made stalking a crime in all 50 states. Stalking across state lines is a federal offense.

THE CRIME OF STALKING

No single legal definition of stalking exists. Some states and the model anti-stalking code (National Institute of Justice 1993) have used component terms and concepts such as the requirement of threat, proximity, intent in the stalker, frequency of contacts, fear in the victim, and reasonableness of the victim's reaction. However, there is little legal consensus about these requirements. The inclusion of fear in the definition of stalking is used to distinguish stalking from harassment and to differentiate legal from illegal behavior. Individuals who did not report experiencing subjective or reasonable fear were less likely to consider behaviors stalking (Owens 2015).

California's anti-stalking law (Cal Pen Code §646.9) states: "Any person who willfully, maliciously, and repeatedly follows or willfully and maliciously harasses another person and who makes a credible threat with the intent to place that person in reasonable fear for his or her safety, or the safety of his or her immediate family…" The statute requires a "credible threat" but no requirement that the defendant had intent to carry out the threat.

States vary in their requirements of intent, threat, and resulting fear. Some states do not require intent on the part of the stalker. Florida considers the subjective reaction of the victim to be adequate. Some states require threatening behavior (e.g., Colorado), while others do not require credible threats (e.g., Arizona). Among states with credible threat requirements, some require an "apparent ability" to cause the harm, while others do not. In terms of fear, some states require actual fear, while other states use a reasonable person standard (a reasonable person would have felt fear). Some states require both a threat and fear (e.g., California), while others require only one of the two. Still other states do not require either (e.g., Hawaii) (Fox et al. 2011; Stalking Resource Center 2015). In 2007, 39 states required a fear element and 19 states required a threat component (Leiter 2007 in Fox et al. 2011). Stalking remains primarily a victim-defined crime. In some instances, individuals can be charged with stalking solely based on another's subjective feelings.

Federal regulation includes the 1996 Stalking Law, 18 U.S.C. 2261(A), which makes it a crime for any person to travel across state lines with the intent to kill, injure, harass or intimidate another person. The accused stalker must also

place that person or a member of that person's family in a reasonable fear of death or serious bodily injury, or cause substantial emotional distress (Cornell Law 2015).

Some have criticized stalking laws as overriding constitutionally protected rights and not differentiating lawful from unlawful behaviors (McAnaney et al. 1993; Boychuk 1994; David 1994; Haas 1994; Guy 1993). This would include actions such as panhandling, the "normal" volatility of relationships, the right to travel, the right to be in public places, and "normal" attempts to communicate between ex-partners. Others feel that the laws have not been protective enough; they justify these statutes on the basis that it allows law enforcement and the judiciary to intervene more effectively and preemptively in potentially lethal domestic violence situations (Bradfield 1998; Radosevich 2000).

EPIDEMIOLOGY

There have been several large community surveys of stalking in the United States (Basile et al. 2006; Baum et al. 2009; Black et al. 2011; Catalano 2012; Breiding et al. 2014).

The 2011 National Intimate Partner and Sexual Violence Survey (n = 12,727) showed a lifetime prevalence of 15.2% in women and 5.7% in men, as well as a 12-month prevalence of 4.2% and 2.1%, respectively (Breiding et al. 2014). This is a slight change from the same survey's 2010 data (n = 16,507) showing prevalence rates of 16.2% in women and 5.2% in men; with 12-month prevalence of 4.3% and 1.3%, respectively (Black et al. 2011). However, these are higher rates than the 1998 National Violence Against Women Survey reporting a lifetime prevalence of 8.1% in females and 2.2% in males, with a 12-month prevalence of 0.4% and 1%, respectively (Tjaden and Thoennes 1998). Studies have generally reflected a range of lifetime prevalence from 2% to 13% in men and 8% to 32% in women (Spitzberg and Cupach 2007). The range in rates is partly affected by the definition of stalking used (stalking behaviors, type of resultant fears, etc.) and the population queried.

The range of behaviors used in questionnaires to assess rates of stalking go from the clearly benign and highly subjective (e.g., leaving unwanted messages, showing exaggerated expressions of affection, trying to be friends with the friend of the victim) to those that are clearly criminal and life threatening (e.g., rape, kidnapping, and using a weapon to subdue the individual). Wright et al.'s (1996) FBI sample of 30 stalking cases that resulted in seven homicides and six suicides is unlikely to have much in common with the 62% of young adults in the community who report being "repeatedly" stalked. Details of stalking studies in random and nonrandom populations are listed in Table 64.1.

Stalkers are mostly men who stalk women, usually an ex-intimate (Spitzberg and Cupach 2007). However, female stalking also occurs. According to the 2006 National Crime Victimization Survey, 43% of males were stalked by a female, and 24% of females were stalked by a female (Baum et al. 2009). These rates are higher than previous studies, and higher than studies in mental health settings (Meloy et al. 2011). In a study of 143 stalkers, Meloy et al. (2011) noted that female stalkers were mostly heterosexual, in their mid-30s, and were single, divorced, or separated. Mental illness was common in female stalkers, most commonly mood disorder, with a high prevalence of borderline personality disorder (Meloy and Boyd 2003). Unlike male stalkers, female stalkers were more likely to stalk male acquaintances, strangers, and celebrities, rather than ex-intimates.

Same-sex stalking is also common. In 1998, Tjaden and Thoennes noted that 60% of male stalking victims were stalked by another male. The 2006 Supplemental Victim Survey indicated that 23.5% of female stalking victims were stalked by a female, and 41.3% of males were stalked by a male (Baum et al. 2009). Based on prior studies, one-quarter of adult stalking may involve same-sex stalking (Strand and McEwan 2011), with higher rates in juveniles (Purcell et al. 2010). In a comparison of same-sex stalking cases (n = 94) and opposite-sex stalking cases (n = 160) from Sweden and Australia, Strand and McEwan (2011) noted that same-sex stalkers were more likely to have a "resentful" or "rejected" motivation. In contrast, opposite-sex stalkers were "intimacy seeking" or "incompetent suitors."

Juvenile stalking remains understudied, though may be different from adult stalking. In one of the first studies of juvenile stalkers (n = 299), a majority of stalkers were male (64%) and victims female (69%), similar to adult studies; however, with a higher proportion of female stalkers. Juvenile female stalkers mostly targeted other females; motivated commonly by bullying and retaliation for perceived injury. Juvenile male stalkers were most commonly motivated by rejection from a break-up (Purcell et al. 2010). Almost all juvenile stalkers knew their victims (98%). Juveniles used direct methods of stalking, including unwanted approaches (76%) and telephone calls (42%). Interestingly, stalking was most commonly seen as an extension of bullying, with 54% of victims being physically attacked (Purcell et al. 2009).

TYPOLOGY

There is no uniform classification of stalking. Stalking, like violence, is a common behavioral pathway that flows from diverse motivations. The sexual predator who follows the child with a well-rehearsed plan to torture, rape, and kill is a stalker; the high school student who simply cannot let go of his ex-girlfriend and insists on staying close to her in the cafeteria and hanging outside of her home in spite of being warned is a stalker; and the homeless individual with schizophrenia who keeps following a stranger in response to auditory hallucinations is a stalker.

Most relevant classifications of stalkers involve some combination of the relationship to the victim and the stalker's motivation. The most influential and known typologies are from Zona et al. (1998), Mullen et al. (2000), and Mohandie et al. (2006) (Racine and Billick 2014). Violence is directly related to intimacy and closeness (Schwartz-Ross and Morgan 1998).

Table 64.1 Stalking studies in random and nonrandom populations

Reference	Sample type	Percentage stalking	Remarks
Australian Bureau of Statistics (1996)	*n* = 6300 (females) Random community	15% lifetime prevalence	40% stalked months to more than 2 years Stalkers most often strangers. Two-thirds asymptomatic
Fremouw et al. (1997)	*n* = 600 college students	30% females 17% males	80% new stalkers 43% females and 24% males dated stalker
Kienlen et al. (1997)	*n* = 341	LAPD/Threat Management Unit	Simple obsessional 217 Love obsessional 87 Erotomanics 17
National Institute of Justice, Tjaden and Thoennes (1998)	*n* = 8000 females *n* = 8000 males Random community	8.1% female, 2.2% male lifetime prevalence	78% victims female 80% stalkers male 81% assaults 31% rapes
Harmon et al. (1998)	*n* = 175 Forensic clinic referrals		Affectionate/amorous 61% Persecutory/angry 31% Violent 46%
Mullen et al. (1999)	*n* = 145 stalkers Self/court referred		Typology: Rejected 58, Intimacy seeker 54, Incompetent 24, Resentful 24, Predatory 8
Tjaden and Thoennes (2000)	*n* = 1785 Domestic violence reports	18.3% females 10.5% males	One in six was stalked; protective orders frequent, stalking victims sustain less physical injury
	n = 5910 victims *n* = 3842 stalkers Police reports	69/100,000 female 20/100,000 male	78% victims female 87% stalkers male
Bjerregaard (2000)	*n* = 788 college students	25% females 11% males	96% females stalked by males One out of three males stalked by males Half ex-intimates; threat of violence: 23.8% females; 13.8% males
Fisher et al. (2000) National College Women Sexual Victimization (NCWSV) study	*n* = 4446	13.1% women reported being stalked since start of school year	Duration average 60 days Three out of ten reported emotional injury 10.3% had forced or attempted sexual contact
Sandberg et al. (2002)	*n* = 62 Adult psychiatric hospital clinical staff		52% harassed, 3% stalked
Spitzberg (2002)	Meta-analysis of 103 studies	Average prevalence: 23.5% women 10.5% men	Average length of stalking: almost 2 years 75% of victims are female
Purcell et al. (2005)	*n* = 1844 Random community		Stalking victims had higher caseness on GHQ-28 than nonvictims, and harassed victims 34.1% met caseness 1 year after stalking ended
Basile et al. (2006)	*n* = 9684 Random community ICARIS-2 phone survey	7% women and 2% men lifetime prevalence	
Baum et al. (2009) Supplemental Victimization Survey 2006	*n* = 65,270 Random community	In a 12-month period, 14/1000 persons age 18 or older were victims of stalking (1.4%)	11% stalked 5 years or more; divorced or separated had highest risk 34/1000

(*Continued*)

Table 64.1 (*Continued*) Stalking studies in random and nonrandom populations

Reference	Sample type	Percentage stalking	Remarks
Mohandie et al. (2006)	*n* = 1005 Nonrandom Three prosecutorial agencies, one police department, one corporate security department	81% of victims were female	73% in private context 27% in public context 28% physical assault 19% used weapons to harm or threaten victim or object of victim 58% of stalkers had precipitant (break-up of relationship or rejection)
Dressing et al. (2007)	*n* = 2000 (1000 women and 1000 men) Random community sample in Germany	11.6% lifetime incidence 17.3% women, 3.7% men	31% physical violence 19% sexual violence
Spitzberg and Cupach (2007)	*n* = 175 studies Meta-analysis	Lifetime: 8%–32% females 2%–13% males	Average stalking duration: 22 months Female victims 60%–80% 79% acquainted with stalker
MacKenzie et al. (2008)	*n* = 122 referred to forensic clinic	93% stalkers were men 69% of victims were women	Stalkers more likely to have insecure attachment styles, particularly fearful style
Purcell et al. (2009)	*n* = 299 juveniles Restraining order applications	64% stalkers were male 69% victims were females	98% pursued known victim 76% used phone calls 67% used text messaging
Dressing and Gass (2010)	*n* = 300 Admitted psychiatric patients	21.7% female, 21% male lifetime prevalence	Stalking course more difficult and violent 46.4% of victims had addictive disorder
Patton et al. (2010)	*n* = 2783 College students		Stalkers significantly higher on insecure-anxious scale, and lower on insecure avoidant scale
Black et al. (2011) National Intimate Partner and Sexual Violence Survey 2010	*n* = 16,507 Random community	16.2% women, 5.2% men lifetime prevalence	Two-thirds of female victims stalked by intimate partner More than one-half of female victims and more than one-third male victims stalked before the age of 25
Catalano (2012) Supplemental Victimization Survey-Revised	*n* = 65,270 Random community	In a 12-month period, 1.5% of persons age 18 or older were stalked	

By integrating concepts of delusional disorders and erotomania and nondelusional/borderline erotomania, Zona and colleagues (1998) divide stalkers into three types:

- *Simple obsessionals*: These individuals constitute the largest group, and form two-thirds of the 200 referrals to the LAPD/Threat Management Unit. Typically this involves the stalking of ex-lovers. Less frequently, obsessive attachments and resentments may involve the stalking of friend, roommates, co-workers, and acquaintances. This group carries the highest risk of violence.
- *Love obsessionals*: These individuals form one out of four of Zona's sample. They are characterized by the absence of any relationship with the victim. Involvement may occur through the media, i.e., star stalkers, but any chance contact may trigger a stalking episode.
- *Erotomanics*: These are predominantly females who believe, against all evidence to the contrary, that the victim loves them. Usually the victim is an individual in a higher station than the stalker.

Mullen and colleagues (2000) classify stalkers into five types:

1. Rejected
2. Intimacy seekers
3. Resentful

4. Incompetent suitors
5. Predatory

The rejected group is similar in composition to simple obsessives. The intimacy seekers are similar to love obsessors and erotomanics. The resentful group includes touchy and paranoid individuals for whom stalking and harassing becomes a way of getting back at co-workers, supervisors, or individuals from some system for perceived persecution. Incompetent suitors feel entitled to a relationship with their interest, regardless of that individual's preference. Predatory stalkers seek excitement from secretly observing their victims. For this group, stalking behaviors may be in preparation for an assault, usually sexual.

Mohandie et al. (2006) suggests a typology using two dimensions: prior relationship to victim and stalking context:

1. Previous relationship
   a. Intimate
   b. Acquaintance
2. No prior relationship or limited contact
   a. Public figure
   b. Private stranger

In a nonrandom study ($n = 1005$), Mohandie et al. (2006) reported that the largest group was the intimate category, at 50%. The intimate group includes cohabitants, married, and sexual intimates. This group was most violent, assaulting more than half of its victims, and one out of three used a weapon to threaten or harm.

BEHAVIORS ASSOCIATED WITH STALKING

Stalking involves intrusive attempts to make unwanted communication with the victim, or to intrude on or control the victim's life. The forms of communication and intrusion are only limited by the stalker's imagination. They include telephone contacts, following, writing letters, and increasingly e-mail and posting information on the Internet. As an example, Jake Baker, a University of Michigan student, was arrested by federal agents for sharing details of his fantasies and plans online to kidnap, rape, and torture a classmate (Branscomb 1995).

Stalkers may show up in places that they know the victim is expected to be, and/or make contact with or ingratiate themselves with the victims' family or acquaintances in an attempt to get close to them. Goods may be ordered on behalf of the victim, services such as the telephone and electricity turned off, and rumors started about the victim. For example, the disgruntled boyfriend of a physician complained to the Board of Medicine that she was improperly prescribing narcotic medications to addicts, compelling an investigation on her. In another case, a young man communicated to his ex-girlfriend's supervisor that the frequent phone calls she gets at work are from clients to whom she is offering her "call-girl" services.

More ominous intrusions include threats of violence, which are reported by 30%–80% of victims. Other examples include directly approaching the victim at his or her home, entering the victim's home to leave threatening mementos, initiating frivolous lawsuits, threatening the victim, threatening family members and friends, damaging property, and killing pets. Extreme cases can escalate to physically assaulting, kidnapping, and raping victims. Ex-intimate stalkers use the broadest range of surveillance and harassment techniques.

The form of communication may reveal something about the stalker and his or her relationship with the victim, real or imagined. Bizarre communication and gifts may suggest that the stalker is psychotic, but this may also be done with the conscious goal of "spooking" the victim. Letter writing is the most common technique employed by erotomanics and love obsessives.

Cupach and Spitzberg (2004) offer eight categories of stalking behavior: "hyper-intimacy, mediated contacts, interactional contacts, surveillance, invasion, harassment and intimidation, coercion and threat, and aggression." Mediated contacts involve the use of technology to communicate. It is unclear how much overlap there is between cyberstalkers and offline stalkers (Bocij and McFarlane 2003, in Spitzberg and Cupach 2007).

Stalking behavior can be prolonged. One-fourth of subjects in the study of Tjaden and Thoennes (1998) were stalked for an average of 1.8 years; delusional and erotomanic stalkers may continue as long as 5 or 10 years (Zona et al. 1998; Mullen et al. 2000). In a meta-analysis of 175 studies, Spitzberg and Cupach (2007) reported an average stalking duration of 22 months.

With advances in technology, the options for the stalker are many. However, stalkers are not abandoning more traditional means of stalking. In the 2006 Supplemental Victimization Survey, 73.2% of stalkers did not use cyberstalking or electronic monitoring (Baum et al. 2009). Similarly, the 2010 National Intimate Partner and Sexual Violence Survey reported that the dominant methods of stalking remained unwanted phones calls and physical approach.

MOTIVATION FOR STALKING

As with domestic violence, stalking is often associated with relationships that involve narcissistic or borderline personalities, pathologic rage (Edelson and Tolman 1992; Meloy 1998), enmeshment, and abandonment rage. The most common reason for stalking is the desire to be with a loved one (Mohandie et al. 2006; Spitzberg and Cupach 2007). Often this is coupled with or alternates with a need for revenge, control, and the desire to hurt or even kill the love object. Stalking behaviors may be maintained by revenge and hatred alone. This concept is neither new nor unusual in that pathologic jealousy and abandonment rage have always been the most common reason why men hurt or kill the women they claim to love (Stone 1989; White and Mullen 1989).

Individuals with paranoid, schizoid, and narcissistic personality disorders may be hypersensitive to or misconstrue communications from co-workers, neighbors, or casual acquaintances. A real or imagined slight becomes an obsession that then results in stalking behavior. Many have personality disorders that make it difficult for them to achieve real friendships, courtship behavior, and intimacy. Over half the stalkers in Mullen's sample (Mullen et al. 2000) had never been out on a date. Individuals who may have had a prior relationship may desperately try to hold on to it. Erotomanics and love obsessives typically have fantasy relationships as a substitute for a real one that they are not able to achieve.

Psychotic motivations may include affection, sexual desire, or the delusional belief that the other person loves them. The motivation may be driven by paranoid, grandiose, or religious delusions. Stalking may occur in response to auditory hallucinations. For example, a homeless individual may follow a jogger wearing a green sweatshirt to his door in response to auditory hallucinations and a delusion that the person is the messiah.

Individuals with intellectual disability and dementia can have trouble exercising appropriate control on their behavior. As a result, they may follow individuals to whom they are sexually attracted, feel affectionate toward, or are drawn by some curiosity or resentment.

Individuals with Autism Spectrum Disorder (ASD) have deficits in communication, social reciprocity, and socialization. ASDs have difficulty reading social cues and may have perseverative behaviors that interfere with social competency (Post et al. 2014). As a result, ASDs may attempt to initiate relationships with socially inappropriate conduct that unwittingly resembles stalking (Stokes et al. 2007). Romantic and sexual urges may be expressed in inappropriate and, at times, bizarre manners in individuals with ASD. ASDs may be over-represented in those who pursue unusual sexual lives, i.e., those whose choice of sexual expression tends to be viewed as "deviant or weird." Such individuals may be viewed as odd/eccentric, mentally disordered, or even criminal, depending on the crime, the period, and the surrounding culture.

Often lacking appropriate awareness of boundaries, ASDs may engage in inappropriate physical contact or attempts at closeness. Consider, for example, the student in high school who grabs the breasts or genitalia of a fellow student; exposing themselves hoping to attract another; or engaging in obsessional following. An indiscriminate approach can also lead to sexual and violent victimization of both males and females. Inappropriate attempts to gain the attention of a potential sexual partner may result in charges of sexual assault, sexual harassment, or stalking claims in the workplace, school, and other settings.

A 2007 study ($n = 25$) suggested that ASDs are more likely to have inappropriate touching and comments, belief that the person of interest must like them, and obsessive interest. They are also more likely to follow the person, pursue in a threatening way, make threats to the person, or threaten self-harm (Stokes et al. 2007).

Stalking sometimes represents a cover for underlying paraphilic disorders. Sexual predators and paraphiliacs, i.e., pedophiles, rapists, sadists, voyeurs, fetishists, and obscene phone callers, may engage in stalking-type behaviors (Lloyd-Goldstein 2000). The following three case examples demonstrate this principle:

- A 27-year-old male is repeatedly arrested and incarcerated for entering a female's home to acquire lingerie for sexual arousal. The prominent sexologist Havelock Ellis described a British soldier who was sexually aroused by the smell of menstrual blood; he was exquisitely sensitive to the smell, and would detect and follow women who were menstruating. On one occasion he was caught as he followed a woman into her tent and attempted to remove her menstrual pad while she was sleeping.
- A 31-year-old male would repeatedly follow women with a video camera, staying at a short distance from them, ultimately following them all the way up to their door. He was later convicted of following, overpowering, and raping a policewoman.
- A 16-year-old male would follow attractive young women on a jogging path while exposing his genitals. He then progressed to physical contact by brushing up against them. Eventually, he followed a woman and tried to rape her, leading to his arrest and incarceration.

PSYCHIATRIC DISORDERS AMONG STALKERS

The majority of stalkers have a mental illness, whereas a minority have a psychotic disorder (Meloy 2007). Cluster B personality disorders of the borderline, narcissistic, and histrionic types are predominant in ex-intimate stalkers. Less often, dependent, schizoid, and paranoid personality disorders may be noted. Substance abuse is common. Antisocial personality is uncommon; the presence of psychopathy should raise concerns about violence. There may also be interplay between psychotic disorder and typology of stalker. For instance, a resentful stalker with a psychotic illness with persecutory delusions may have increased risk of violence. However, an intimacy-seeking stalker with an erotomanic delusion may have decreased risk of violence (Mullen et al. 2006).

VICTIMS OF STALKING

Some 80%–90% of stalking victims are women. On the flip side, 80%–90% of stalkers are men. Stalking has been described in all ages, including adolescents (McCann 2001; Purcell et al. 2009).

The most common victims of stalking are young women in their reproductive years, who have had a sexual relationship with their stalker. As in other victims of domestic violence, some may have enmeshed, dependent,

sadomasochistic relationships with the perpetrator. Often there is a history of childhood abuse (Bowlby 1979; Downs 1996; Gelles 1997; Goodyear-Smith and Laidlaw 1999). This group is at the highest risk of violence, including lethal violence. Physical assault, rape, and stalking often start even prior to the separation. Physical violence may occur in 20%–30% of stalking cases (Spitzberg and Cupach 2007).

Victims of nonintimate stalkers do not fit one particular profile. Those who are stalked by intimacy seekers and love obsessionals are often visible and appealing. Victims may include co-workers, roommates, casual acquaintances, and complete strangers. Therapists and physicians are especially prone to being stalked as a result of having to deal with emotionally needy people. In a meta-analysis of physician stalking studies, Nelson et al. (2015) noted a prevalence rate of 1.5%–25.1% (with one study showing 68.5%).

People with mental illness also seem to be vulnerable to stalking. In a German study of 300 patients admitted to a psychiatric hospital, 21% of the patients had been stalked, nearly twice as high of the German general population (11.6%). In addition, the course of their stalking was more difficult and violent (48.4% had been physically attacked and 83.9% had been struck) (Dressing et al. 2011).

Stalking can cause serious disturbances in emotional, social, interpersonal, and work functioning. Posttraumatic stress disorder has been reported in 37%–60% of stalking victims. Victims commonly report depression, anxiety, insomnia, somatization disorders, and substance abuse. A random community sample comparing victims of stalking, brief harassment, and nonvictims noted higher scores for severe depression in stalking victims, with 10% of victims endorsing recent SI (Purcell et al. 2005). Longer durations of stalking may be more damaging. Stalking lasting more than 2 weeks was associated with higher rates of anxiety, depression, and posttraumatic symptoms (Purcell et al. 2005). In addition, stalking victims who were threatened were significantly more likely to have PTSD symptoms than victims who were not. Victims who were physically harmed did have more PTSD symptoms, but the difference was not statistically significant.

Hall (1995) noted self-identified stalking victims as becoming aggressive, paranoid, and fearful. One-third of the females, and one-fifth of the men of domestic violence stalking victims sought psychiatric help (Tjaden and Thoennes 2000). As a result of stalking, victims may move, change jobs, stop working, change their usual routes, isolate, and, in some instances, arm themselves. The economic cost of stalking can be high. More than half of stalking victims lost five or more days at work (Baum et al. 2009). The negative emotional impact of stalking on the victim may persist even after the stalking has ended. Purcell et al. (2005) reported that more than one-third of stalking victims continued to have anxiety and depression a year after the stalking (34.1% met caseness for GHQ-28). The most common fear of stalking victims is the uncertainty of what would happen next (Baum et al. 2009).

Stalking victims often feel they have less power to address their stalking (Spitzberg and Cupach 2007). Cupach and Spitzberg (2004) noted five categories of victim coping: "moving with, moving against, moving away, moving inward, and moving outward." "Moving with" refers to efforts to negotiate with the stalker. "Moving against" refers to efforts to deter the stalker. While "moving inward" is coping by focusing on the self, including denial or buying a gun, "moving outward" is the seeking of outside help.

Self-identified victims recruited through the media (Hall 1995; Brewster 2000) or through support groups such as incest survivor groups (Kamphuis and Emmelkamp 2001) may be prone to exaggerate, fabricate, falsely attribute, or, in some instances, be delusional about being stalked.

FORENSIC ASPECTS OF STALKING

Stalking, like sex offending, is recognized as both a psychiatric and criminal problem. Many states and the model anti-stalking code specifically recommend mental health evaluations on those charged with the crime of stalking. Referring parties may request opinions on various aspects of stalking including the following:

- Assessment of criminal competency, i.e., insanity, diminished capacity, the ability to form specific intent
- Evaluation of stalking victims, i.e., mental state of victims who killed in self-defense (battered wife syndrome); claims of posttraumatic stress disorder and other psychiatric disorders as a result of stalking issues of false victimization
- Appropriateness of *Tarasoff* warning when clinicians become aware of a patient stalking a specific victim; issues to hospitalize or release stalkers
- Psychiatric worker's compensation evaluation of employees who claim to be stalked in the workplace; stalking and risk of workplace violence by disgruntled employees
- Violence risk assessment of stalkers
- Recommendations regarding civil commitment, rehabilitation, and treatment for stalkers
- Threat management consultations
- Stalking/child abduction and high-conflict child custody cases
- Assessment of paraphilic and predatory stalkers

Assessment

The assessment procedure includes the following:

- Psychiatric examination, including record review and collateral information, i.e., medical, psychiatric, police, work records
- Current psychiatric, chemical dependency, and medical problems
- Past history and response to treatment; motivations for stalking behavior; history of recent losses

- Psychological tests including Minnesota Multiphasic Personality Inventory-2 (MMPI-2)/ Minnesota Multiphasic Personality Inventory-2 Restructured Form (MMPI-2-RF), Millon Clinical Multiaxial Inventory-III (MCMI-III), Hare Psychopathy Check List-Revised (PCL-R)
- Violence risk assessment
- Family and social support
- Treatment recommendations, i.e., civil commitment, inpatient, outpatient
- Prognosis

Risk assessment

Stalking is a common behavior driven by various motives. Similar to a headache that may stem from mild sinus congestion or a life-threatening brainstem hemorrhage, some situations of stalking may represent grave danger. Therefore, there cannot be one risk assessment tool for stalking. Rather, the empirically tested and actuarial data available from different groups should be considered, i.e., the Danger Assessment Instrument for Batterers (Saunders 1995), Violence Risk Appraisal Guide (VRAG) (Quinsey et al. 1998), PCL-R (Hare 1991), the Stalking Risk Profile (SRP) (McEwan et al. 2011), Stalking Assessment and Management (SAM) (Kropp et al. 2011), and the Static-99 for sex offender recidivism (Hanson and Thornton 1999). General factors in violence risk assessment should also be noted (Monahan and Steadman 1994).

Mullen and colleagues (2006) suggest a "Stalking Risk Profile" that involves examining five domains: (1) the stalker and victim relationship; (2) motivation of the stalker; (3) characteristics of the stalker including psychology, psychopathology, and social context; (4) vulnerabilities of the victim; and (5) the general context of the stalking, including legal and mental health issues.

Factors likely to increase the risk of assault in stalkers (Palarea et al. 1999; Mullen et al. 2000; Rosenfeld and Harmon 2002; Rosenfeld 2004 in Meloy 2007; McEwan et al. 2009; McEwan et al. 2011) include the following:

- Substance abuse
- History of criminal offending including sexual and violent offending
- Male gender
- Making threats of violence and suicide
- The presence of personality disorder, especially borderline, narcissistic type
- Pursuing an ex-intimate
- Long-term preoccupation with victim
- Being unemployed or underemployed
- Being socially isolated
- Having high levels of anger directed at the victim
- Having an intense sense of entitlement
- Fantasizing about and planning assaults
- Possessing weapons and having a history of familiarity with weapons
- Access to victim; physical approaches to victim in multiple settings
- Sense of desperation to resolve situations; "crisis periods," e.g., protective disorders, police confrontation, threat of arrest or incarceration; current stressors such as death of loved one, job loss, loss of child custody/visitation
- History of noncompliance to treatment
- Explicit threats, current or prior (except for public figures)
- Less than 30 years old
- Less than a high school education

Mullen et al. (2006) suggested that stalking victims have three types of risks: (1) not knowing when the stalking will end or if it will start again; (2) whether the victim will have significant social or psychological damage; and (3) whether physical or sexual harm will occur.

In the 2006 Supplemental Victimization Survey ($n = 65{,}270$), most stalking occurred before the age of 25 (most frequent from ages 18–19 and 20–24) and declined with age (Baum et al. 2009). Stalking is also associated with income, with an increased risk with lower income.

Stalkers have a high rate of recidivism. In a 9-year study of 78 offenders, Eke et al. (2011) reported that 56% were charged with new stalking offenses and 33% of these stalkers committed physical violence. Predictors of violent recidivism included younger age at first offense, criminal history, prior failure on conditional release, and history of substance abuse problems. Similarly, in a study of 148 stalking and harassing offenders, Rosenfeld (2003) noted that 49% reoffended, with 80% reoffending during the first year. Stalkers with personality disorders (cluster B) and substance use disorders were at highest risk of recidivism.

Risk management

Meloy (1998) recommends the following risk management approach:

- Use a team approach including law enforcement, mental health professionals, and the courts, and personnel necessary to provide safety to the victim.
- Emphasize the victim's need to show responsibility for personal safety.
- Document specifics of contact so as to establish a course of conduct on the part of the perpetrator that defines stalking and the responses of fear in the victim.
- The victim should not initiate or have contact with the perpetrator, as it will reinforce the behavior.
- Obtain restraining orders to suppress approach behavior, also, to emphasize the continuity of the course of conduct and to document fear. Victims should be advised that restraining orders in some instances may provoke violence.
- Law enforcement and prosecution: File appropriately all police reports and take steps to help prosecute, even when it is troubling.
- Treatment of stalkers: For those with Axis I disorders, consider benefit from antipsychotic and mood stabilizers. Delusional disorders are difficult to treat.

Personality disorders likewise may be difficult to treat, but may benefit from the group therapy format, i.e., relapse prevention program similar to those used with sex offenders and domestic violence.
- Perform periodic violence risk assessment.
- Recognize, prevent, and contain situations ("dramatic moments"), which are expected to cause narcissistic injury in the stalker. This will result in increased risk of violence. Situations include protective orders, denied child custody visits, and police and judicial confrontations.

False victimization

False victimization often involves claims of physical illness, e.g., factitious disorder, factitious disorder by proxy, physical assault, sexual harassment, and sexual assault. Kanin (1994) noted false allegations of rape in about half of a sample of female college students. False claims of stalking are not uncommon, and have been reported in the law enforcement literature (Artingstall 1999). Mullen et al. (2000) reported 18 cases among their series of 145 victims, and Zona et al. (1998) reported six among a series of 341. These actions may be carried out for attention, malice, or from psychotic delusions. False victims tend to seek legal and psychiatric intervention earlier, and often show significant anger. Improbable stories, repeated episodes of stalking, and multiple stalkers—especially in individuals with a history of illness behavior, unsubstantiated disabilities, borderline personality, suspicious previous history of victimization, and litigious tendencies—should raise concerns regarding the authenticity of these claims.

Another form of false victimization is "paper abuse" or "paper stalking." This occurs by filing false and frivolous lawsuits with the intention to control the victim, to force contact, to financially drain, and to scare the victim (Miller and Smolter 2011 in Belknap et al. 2012). Miller and Smolter (2011) also note that once the legal system is recruited into the stalking, phone calls and e-mails from the stalker to the victim would be considered normal, or legal.

SUMMARY

Stalking continues to be seen by many as a crime of violence, enacted by mentally ill individuals who are obsessed with celebrities. Since 1990, there has been increased study, and more rigorous study, of stalking and stalking victims. From having been in the shadows as an exotic psychiatric condition, stalking has been re-cast as a terrifying "epidemic." Distortions of data and political agendas have made stalking out to be perhaps more pervasive and lethal than the data support. The risk of violence cannot be assessed on the basis of stalking alone, but on the traditional risk assessment instruments.

SUMMARY KEY POINTS

- Most victims are women and most perpetrators are men, usually ex-intimates.
- Cluster B personality traits (borderline, histrionic, narcissistic) predominate ex-intimate stalkers.
- Females more likely to stalk acquaintances, strangers, and celebrities.
- Posttraumatic stress disorder is common in stalking victims, as well as depression, anxiety, insomnia, somatization disorders, and substance abuse.
- Physical violence occurs in 20%–30% of stalking cases.
- Most stalkers have mental health diagnoses, but only a minority have psychotic disorders.

Cyberstalking and the Internet age

KANG CHOI AND MOHAN NAIR

INTRODUCTION

The rapid pace of technology and simultaneous life in both offline and online worlds increases our ability to express ideas and obtain information. However, the Internet age also increases our exposure, with increased risks to our personal information (including where we are, what we say, and to whom we communicate). As our identities expand into cyberspace, so too do the potential tools for use by stalkers.

EVOLVING TERMS: CYBERSTALKING/ CYBERHARASSING/CYBERBULLYING

Cyberstalking is often discussed in relation to, and sometimes interchangeably with, the terms *cyberharassing* and *cyberbullying*. Although there are no universally accepted definitions of these terms, there are general differences. Cyberstalking is the stalking of another person via the Internet, e-mail, and other electronic devices (Department of Justice 2001). Stalking generally refers to repeated, threatening behavior or conduct that causes actual or reasonable fear (Department of Justice 1998). The cyberstalker's motivation is often to control the victim, much like stalkers who employ offline techniques (Department of Justice 2001).

In contrast, cyberharassing refers to the use of electronic means to annoy, alarm, or cause substantial emotional stress for no legitimate purpose (Fukuchi 2011; Caplan 2013). Unlike cyberstalking, cyberharassing does not require a threat or resultant fear (although legal definitions vary). In addition, the motivation of the harasser may be to frighten or embarrass the victim.

Cyberbullying is the use of electronic communication to further aggressive, repeated behavior in a situation of unequal power, as well as to hurt or embarrass. Cyberbullying usually refers to behavior between minors but can also include adults (Ruedy 2008; Olweus 2011). In contrast to traditional bullying, cyberbullying is not limited to schools, can occur anywhere, and may have greater impact on the victim (Ruedy 2008). Cyberbullying can be divided into several categories: flaming, harassment, denigration, impersonation, outing, trickery, exclusion, and cyberstalking (Lexis 2012).

Cyberstalking, cyberharassing, and especially cyberbullying, have attracted increased media attention due to several well-publicized teen suicides. Intense harassment of teens in the wake of upsetting or embarrassing communications related to text messaging, sexting, e-mails, posting of videos, and social networking sites has also garnered considerable media attention.

In 2006, a 13-year-old Missouri teen, Megan Meier, hanged herself after she received disparaging posts on MySpace, including "the world would be a better place without you" and negative text messages from a boy she had befriended on MySpace, known to her as "Josh." "Josh" was actually a fictional character created by an adult neighbor, Lori Drew, her teenage daughter (former friend of Megan), and an employee. Lori Drew was charged with violating the MySpace terms of agreement, though was eventually acquitted on criminal charges related to violating the federal Computer Fraud and Abuse Act (CFAA) (Ruedy 2008).

In response to public outcry, Missouri passed Megan's Law in 2008, criminalizing any communication used to harass a person. In that same year, U.S. Representatives Kenny Hulshof (R-Mo) and Linda Sanchez (D-Ca) introduced the Megan Meier Cyberbullying Prevention Act. The federal measure included language criminalizing communications with the "intent to coerce, intimidate, harass, or cause substantial emotional distress to a person; using electronic means to support severe, repeated, and hostile behavior" (H.R. 6123, 110th Cong. §3(a) [2008]). The measure failed to pass because it was considered overbroad (Lipton 2012). Moreover, in 2012, the Missouri Supreme Court struck down a significant portion of Megan's Law as also being overbroad.

Cyberbullying

Cyberbullying is a significant problem. In many respects, the issue goes beyond school grounds with greater impact than traditional bullying due to the ever-present Internet and cell phones, ease of instantaneous and wide dissemination,

anonymity emboldening bullies, and the permanence of items posted to the Internet (Ruedy 2008).

According to a recent survey, 92% of U.S. teenagers go online daily, and 89% of U.S. teenagers use at least one social networking site, primarily Facebook and Twitter (Lenhart 2015). Despite high participation online, cyberbullying is relatively low (with the caveat that some vulnerable groups underreport, such as gay students [Lexis 2012]). In a 2011 Pew Research Center study, 19% of teens surveyed were bullied in the past year, with the majority being bullied in person (12%). Nine percent were bullied with text messages, 8% bullied online, and 7% bullied over calls (Lenhart et al. 2011). Similarly, the 2009 School Crime Supplement to the National Crime Victimization Survey of 7,066,000 U.S. students (12 through 18 years old) found that 28% of students had been bullied at school, and 6% had been cyberbullied. However, other studies have reported rates as high as 40% (Hinduja and Patchin 2010).

As of 2011, 44 states had passed anti-bullying policies in public schools, 31 of which had laws addressing electronic harassment, and 6 directly addressing cyberbullying (Lexis 2012). By 2013, 49 states had anti-bullying laws with 9 states addressing cyberbullying (Hinduja and Patchin 2013). However, in a rush to protect children, there is the risk of criminalizing normal teenage behavior, such as "drama" acted out in cyberspace. Teenagers see drama as interpersonal conflicts played out in front of an audience, particularly social media sites. Unlike bullying, drama can occur without an imbalance of power, and can occur between friends; and may be an important part of teenage life and coping (Marwick and Boyd 2011). It is possible that "banter" between friends could be seen as cyberbullying (Lipton 2012). A real-world example of criminalizing teenage behavior is sexting.

SEXTING

Sexting involves sending suggestive nude or partially nude photos via text message to another person (Lenhart 2009). Cell phones have made this more common. In 2009, 75% of teens, 12 through 17 years old, owned a cell phone, with 66% of teens using text messaging. Of cell phone owning teens, 4% sent nude or nearly nude pictures, and 15% received nude or semi-nude pictures of someone they knew (Lenhart 2009). A 2008 online survey reported higher sexting rates: 20% of teens sent or posted nude or semi-nude pictures (mostly to a love interest or love relation). Thirty-nine percent of teens sent or posted sexually suggestive messages (The National Campaign to Prevent Teen and Unplanned Pregnancy 2008). By 2015, 88% of teens owned or had access to a cell phone or smartphone, with 90% using texting (Lenhart 2015).

Sexting can occur between two minors in a relationship. However, the images can easily be disseminated to other parties, often out of anger toward the other party. Sexting can be seen as part of sexual exploration, flirtation, and foreplay (Lenhart et al. 2011; Tang 2013). Those who are anxious or uncomfortable with face-to-face contact and physical proximity, or even talking to another person, are more likely to engage in this as part of courtship behaviors. Some states have prosecuted minors under child pornography laws, creating minor sex offenders, while other states have created lesser misdemeanors for minors. "Romeo and Juliet carve-outs" for minors in a relationship have been proposed to avoid prosecution of teens as sex offenders based on relatively typical teenage behaviors (Tang 2013).

CYBERSTALKING

Studies suggest that the prevalence of cyberstalking is 1%–43%, depending on the definitions used and the population studied (Cavezza and McEwan 2014). In a 12-month study of stalking, the 2006 Supplemental Victimization Survey found that one in four stalking victims had some form of cyberstalking (83% by e-mail, 35% by instant messaging) (Baum et al. 2009). In an online survey of 6379 members of a German social network, Dressing et al. (2014) reported a cyberstalking prevalence of 6.3%. Dressing suggests that the assumption that cyberstalking has higher prevalence than offline stalking may be due to less stringent definitions of stalking used in cyberstalking studies. In addition, there is likely crossover between online and offline stalking. In a comparison of offline and online stalkers, a majority of cyberstalkers used offline methods as well, suggesting that the Internet is an added tool for traditional stalkers (Cavezza and McEwan 2014). Details of selected random and nonrandom cyberstalking studies are listed in Table 65.1.

Similar to traditional stalking, most cyberstalkers are male ex-intimates. The victims are mostly women (Department of Justice 2001; Dressing et al. 2014). Victims of cyberstalking suffer negative emotional impacts similar to offline stalking victims (Dressing et al. 2014). However, the harms may be greater due to the ease of stalking in cyberspace (e.g., frequent contacts, wide dissemination, recruitment of other stalkers) and the permanent nature of its content. In a forensic sample ($n = 72$), Cavezza and McEwan (2014) did not find major differences between characteristics of offline and online stalkers. Cyberstalkers were not more likely to have multiple victims and not more violent (actually had lower rates of physical violence). Dressing et al. (2014) argues that cyberstalking is a "variant" of offline stalking rather than being a distinct entity. Most states have treated cyberstalking as an extension of traditional stalking. Forty-six states have expanded their offline stalking legislation to include "electronic forms of communication" (Baer 2010).

However, there are some significant differences between offline and online stalking, suggesting that cyberstalking may be distinct (Goodno 2007; Baer 2010). The ability to stalk in cyberspace creates advantages and incentives for the stalker, while complicating legislative efforts. Internet and wireless communication greatly reduce the amount of effort, cost, and energy required to stalk, which may induce more people to stalk. Technology allows for instantaneous and wide dissemination of information. In addition, the cyberstalker can be anyplace in the world and can even remain largely anonymous, which may embolden the stalker (Goodno 2007).

Table 65.1 Cyberstalking studies in random and nonrandom populations

Study	Sample size	Prevalence	Comments
Sheridan and Grant (2007)	*n* = 1051 Self-identified stalking victims	47.5% reported being harassed on the Internet 7.2% were deemed to be cyberstalked	No significant difference between online and offline stalking
The National Campaign to Prevent Teen and Unplanned Pregnancy (2008)	653 teens (ages 13–19) 627 young adults (ages 20–26) Random community		20% of teens sent or posted nude or seminude pictures (22% girls, 18% boys) 39% of teens sent or posted sexually suggestive posts (37% girls, 40% boys) 71% of girls and 67% of boys sent sexually suggestive content to boyfriend or girlfriend
2009 School Crime Supplement to the National Crime Victimization, Department of Education (2011)	*n* = 7,066,000 U.S. students (12–18 years old) Random community		28% of students had been bullied at school 6% had been cyberbullied
2006 Supplemental Victimization Survey, Baum (2009)	*n* = 65,270 (ages 18 and older) Random community	One in four victims stalked subjected to cyberstalking	Of those cyberstalked, e-mail used in 83%, instant messaging in 35%, with electronic monitoring in 1 in 13 victims (spyware, cameras, bugs, GPS)
Pew Research Center, Lenhart et al. (2011)	*n* = 799 teenagers (12–17 years old), telephone survey		95% of teens are online 80% of online teens use social media 69% of teens felt that peers were mostly kind on social network sites 19% bullied in the last 12 months (12% in person, 9% via text message, 8% via online, 7% via voice calls)
Dressing et al. (2014)	*n* = 6379 members of German social network site	Cyberstalking prevalence of 6.3%	69.4% of cyberstalkers were male 35% involved ex-partner stalking 32% of cyberstalking lasted up to 1 month
Cavessa and McEwan (2014)	*n* = 72 (36 cyberstalking offenders, 36 offline stalkers)		Both groups targeted women with primary motivation to get revenge for a break-up or to continue a relationship
Pew Research Center, Lenhart (2015)	*n* = 1060 parents *n* = 1060 teens (13–17 years old) Random community		92% of teens go online daily 88% of teens have or have access to a cell phone or smartphone (90% send texts)

Importantly, the cyberstalker can impersonate his or her victim online, writing inflammatory comments, distributing inappropriate content, or sending invitations for sex or violence that are attributed to the victim. In addition, the Internet allows for the incitement of third-party harassers, or an avenue to request that others do the stalking (Goodno 2007; Ruedy 2008). For example, in the 1999 *State of California v Dellapenta* case, the first case prosecuted under the 1998 California Cyberstalking law, a female victim rejected the romantic advances of an older male. The male stalker impersonated the female victim online in websites and chat rooms, posting advertisements for sex—stating that the victim had a rape fantasy and wished to be raped. In addition, the cyberstalker posted the victim's actual phone number and home address. Several men knocked on her door late at night wishing to rape her, causing the victim severe emotional distress (Miller and Maharaj 1999; Zeller 2006).

The incitement of third-party stalkers can also be achieved through inflammatory websites, such as the "Nuremberg Files." In the 2002 Ninth Circuit Court case, *Planned Parenthood of the Columbia/Willamette, Inc. v. American Coalition of Life Activists*, an anti-abortion group made a poster, "Dirty Dozen," including the names and addresses of abortion doctors with a $5000 reward for information that would result in the arrest, conviction, or loss of medical license for these physicians. This poster grew

to a website called the "Nuremberg Files" which listed the names of physicians, abortion supporters, and noting who on the list had been murdered or injured. The court ruled that the website was a "true threat" and not protected by the First Amendment (Ruedy 2008).

The incitement to harass or stalk can also be unintentional. For example, a Quebec teenager, Ghyslian Raza, filmed himself in a pretend light saber battle imitating a movie, *Star Wars: Episode I—The Phantom Menace*. Fellow students uploaded the video, which was then picked up by the general media. He was dubbed the "Star Wars Kid" and became the target of mockery in the media and intense harassment at school, causing him to finish his high school semester in a psychiatric facility (Wired.com 2003). Also, proxy stalkers, such as friends or family, can be used when the primary stalker is not able to stalk (Melton 2004; Belknap et al. 2012). The case below provides an example of how cyberstalking can progress to actual physical stalking behavior.

The day after she was seen by a dentist, a 23-year-old female started receiving prodigious amounts of e-mail from him; the e-mails, which started at 3 o'clock in the morning the day after her visit, provided extreme personal information, made requests for similar information from her, and expressed sexual fantasies. Following the messages, the dentist started showing up in places that he expected her to be, based on conversations they had in the office. He began to show up at her workplace, telling her that he just happened to be in the area. At one point he visited her at home, allegedly to follow up on a dental problem, and attempted to make physical contact with her at the time she was there, leading her ultimately to seek legal help.

Free speech and cyberstalking

The biggest challenge to cyberstalking laws is the First Amendment. Cyber communications (texts, images, videos) are considered speech. Any restriction of speech content is subject to First Amendment analysis and must be narrowly tailored to avoid being overbroad (impinging on existing protected speech) or vague (must be clear what is being prohibited) and must meet a compelling government interest, or strict scrutiny (Major 2012; Young 2013). Freedom of speech is not absolute. Unprotected speech includes things such as obscenity, defamation, fraud, incitement, true threats, or speech integral to criminal conduct (Shimizu 2013; Young 2013).

Another argument used to curtail speech is the "captive audience" doctrine, which argues that a person cannot be forced to listen to undesired speech (Young 2013). However, the assumption in a public space, including the Internet, is that the individual can choose not to see or hear the message (Major 2012). Some argue that technology and the omnipresence of phones and Internet may create a sense of inescapability or of being held captive.

In 2006, Congress amended the Interstate Stalking Statute (18 U.S.C. §2261A) to include stalking behavior through the Internet (Interstate Stalking Act 1996). Congress also criminalized conduct with the intent to harass, broadening the initial requirement of causing a reasonable fear of death or serious injury. As a result, causing substantial emotional distress would now violate the Cyberstalking Statute (Young 2013).

In the 2012 case of *U.S. v. Sayer*, Sayer created fake social media accounts and advertisements in his ex-girflriend's name that requested sex with men. Sayer uploaded private sex videos they had made when dating and published her phone number and address. The District of Maine Court held that Sayer had violated the federal Cyberstalking Statute and did not have a First Amendment defense because his speech fell into the exception of "true threats" (Young 2013). In May 2014, the U.S. Court of Appeals, First Circuit, upheld the decision. The federal Cyberstalking Statute is likely to be upheld when there is a threat that includes specific identifying information and instructions on how to do the harm (Smolla and Nimmer 1989; Young 2013).

Most recently, in a June 2015 opinion, the U.S. Supreme Court addressed the question of Internet threats in *Elonis v. United States*. Elonis posted rap lyrics on Facebook describing violence against his separated wife, co-workers, a kindergarten class, and law enforcement. Elonis, under the pen name, "Tone Dougie," wrote disclaimers that his writings were "fictitious." However, both his wife and former employer felt threatened by these posts, which resulted in Elonis being fired from his job and his wife filing a restraining order. Elonis was convicted of violating five counts of the federal Interstate Communication Act (18 U.S.C. §875(c)), which makes it criminal to transmit in interstate commerce "any communication containing any threat…to injure another person."

After appeal, the Third Circuit Court upheld Elonis's conviction on grounds that "intent" only required what the defendant understood and if a reasonable person would have seen the communication as a threat. The U.S. Supreme Court overturned the ruling, opining that although intent is not explicitly required in 875(c), criminal statutes are presumed to have an intent requirement. In other words, the prosecution had to demonstrate that Elonis intended to threaten his wife, or that he would know that his wife would feel threatened. The court appeared to consider the nuances of written communication, as well as First Amendment implications. This decision may impact current and future cyberstalking statutes that solely rely on a victim's subjective perception of threat or a reasonable person standard of fear.

SUMMARY

Cyberstalking has received increased media attention as technology has permeated almost every aspect of our lives. The harms caused by cyberstalking are significant and can potentially be more damaging than their offline counterparts. However, the increase in

cyberstalking has not resulted in a parallel increase in violence, despite public perception. In a drive to protect against these harms, society runs the risk of restricting protected speech, as well as criminalizing common human behavior.

SUMMARY KEY POINTS

- Cyberstalking is the stalking of another person using the Internet, e-mail, and other electronic devices.
- The prevalence of cyberstalking ranges from 1% to 43%; cyberbullying prevalence ranges from 6% to 40%.
- Sexting is common (20% of teens sent or posted nude or semi-nude photos of themselves), with the majority directed toward a boyfriend, girlfriend, or love interest; sexting has at times been prosecuted as a sex crime.
- Similar to traditional stalking, most cyberstalkers are male and the victims are mostly female; cyberstalkers are usually ex-intimates.
- Technology greatly reduces the effort, cost, and energy required to stalk, and offers greater anonymity and reach of the stalker (who can be anywhere in the world).
- Anti-cyberstalking legislation must not impinge on Free Speech and has most frequently been upheld on the ground of "true threats," which is unprotected speech.

Mental illness and firearms

AMY BARNHORST

INTRODUCTION

The relationship between mental illness and firearm violence has long been a contentious topic. The Second Amendment to the U.S. Constitution protects the right to bear arms. However, over time, legislation has restricted that right in the interest of public safety. Often this legislation passes in the wake of tragic (but statistically anomalous) events, reflecting the challenges associated with predicting and preventing violent behaviors. People with mental illness are one group whose Second Amendment rights have been limited in the name of safety. However, in practice, this intervention has been fraught with complexity and resulted in equivocal benefits.

STATISTICS OF FIREARM DEATHS IN THE UNITED STATES

According to Centers for Disease Control and Prevention (CDC) data, in 2013, 11,208 homicides occurred by firearms (CDC Fast Stats). The majority of homicides by firearm are single-victim crimes, related to gang activity or interpersonal arguments, or occurring during the commission of other felonies (Federal Bureau of Investigation 2012). In contrast, mass shootings account for a fraction-of-a-percent of firearm homicides. In 2013, there were four public mass shootings (four or more homicides during a single event) with 27 fatalities (*USA Today* 2013). This represents less than 0.001% of the firearm-related deaths in the United States that year.

While homicides garner more public and media attention, suicides compose the majority of U.S. firearm fatalities. In 2013, there were 21,175 firearm suicides in the United States, accounting for 65% of firearm fatalities (CDC Fast Stats 2015).

Not only are the majority of firearm deaths suicides, the majority of suicides are committed with firearms. More adults successfully complete suicide in the United States with guns than with all other methods combined (CDC Fast Stats 2015). This may be attributable to the fact that over 90% of suicide attempts with a firearm are fatal (Miller et al. 2004).

Multiple case-control studies have shown that having a gun in the home is a substantial risk factor for completed suicide (Brent et al. 1991; Kellerman et al. 1992; Wiebe 2003). One meta-analysis of 14 studies showed an adjusted odds ratio of 3.24 (95% CI, 2.41 to 4.40), indicating that people with firearm access are over three times more likely to complete suicide than those without (Anglemyer et al. 2014). Although this correlation does not necessarily imply causation, restricting the public's access to firearms has been shown to be an effective strategy in reducing suicides in both the District of Columbia and Switzerland (Loftin et al. 1991; Reisch et al. 2013).

MENTAL ILLNESS AND VIOLENCE

The public often presumes that people with mental illness are violent, and media coverage of public shootings tends to perpetuate this belief (Angermeyer and Matschinger 1996). However, research indicates that people with severe mental illness are more likely to be victims of violent crime than perpetrators (Choe et al. 2008). They are also more likely to be victims of violence than are other members of the population (Hiday 1999).

Rates of violence by mentally ill people appear elevated in many studies, but concomitant substance abuse consistently emerges as a confounding factor. Data from the MacArthur Research Network on mental illness and violence show that people discharged from psychiatric hospitals who do not have a history of substance abuse commit violent acts at the same rate as matched community controls. People with substance abuse issues, with or without concomitant mental illness, demonstrate higher violence rates than matched community controls. However, people with mental illness are more likely to have substance abuse disorders than people without mental illness. This confounding variable leads to an overall increase in the prevalence of violent acts perpetrated by mentally ill people (Steadman et al. 1998). Multiple other studies have corroborated that substance abuse is a more significant risk factor for violence than mental illness, and that higher rates of substance abuse among the

mentally ill may artificially inflate the correlation between violence and mental illness (Elbogen and Johnson 2009; Martone et al. 2013).

Even among people with severe mental illness who commit acts of violence, there is little evidence that interventions by mental health professionals would have prevented the act. In the retroactive study of homicide defendants, 37% had any prior psychiatric contact; however, only 8% had been seen in an outpatient psychiatric setting in the 3 months preceding the act (Martone et al. 2013). This suggests that relying primarily on the intersection of these individuals and the mental health system is not sufficient.

Nonetheless, the mental health system is often identified as the solution for preventing mass shootings. In the wake of the Aurora movie theater shooting, CBS News ran a story entitled, "Theater attack prompts new Colorado mental health law" (CBS News 2013) After the 2014 Isla Vista shooting, an *SF Gate* headline read, "Isla Vista rampage adds urgency for mental illness laws" (*SF Gate* 2014). Implied in these headlines is a failure of the mental health system to take adequate measures to prevent such events.

However, putting the onus of violence prevention on the mental health system may have an unforeseen negative impact on people's civil liberties. Prospective attempts to identify potential attackers lack specificity, and incidents of violence, especially mass violence, are statistically rare. Research-borne actuarial tools lose their potency when applied by clinicians to patient populations whose background risk is low. Therefore, large numbers of people would need to be involuntarily detained and their civil liberties revoked in order to prevent one mass casualty incident (Buchanan 2006).

Legislation often passes in the wake of public shootings that specifically restricts firearm access by people with mental illness. The public perception of the causal role of mental illness in mass shootings may redirect the legislative focus away from violence prevention policies that rely on evidence-based risk assessment (Appelbaum 2006). Instead, specific restrictions may be targeted at persons with mental illness as a broad category, despite the vagueness of this descriptor and the fact that the majority of gun deaths in the United States are not perpetrated by persons with known mental illness (Applebaum and Swanson 2010).

In addition to misguiding legislation, reinforcing the perception of a strong link between mental illness and gun violence can increase the stigma of mental illness. One study examined public perceptions of violence potential in the mentally ill as influenced by media coverage of mass shootings. Researchers assigned a group of 1797 people either to read a fictional news story about a mass shooting perpetrated by a person with serious mental illness, or to a control group that did not read the article. Both groups were then asked to answer questions about perceived dangerousness of persons with mental illness and their level of support for legislative proposals to restrict firearm access in that population. Participants who read a news stories about the mass shooting were less likely to be willing to have someone with severe mental illness as a neighbor or a co-worker. They also endorsed a higher perceived level of dangerousness of people with mental illness than those who did not read one of the articles. In addition, they were more likely to support firearms restrictions targeted at the mentally ill (McGinty et al. 2013).

The public stigma resulting from perpetuating the perceived link between mental illness and violence likely creates obstacles to stable housing and employment for people with mental illness. In addition, this stigma becomes internalized by patients and inhibits people with mental illness from seeking and engaging in necessary treatment (Ritsher and Phelan 2004). Therefore, misguided attempts to increase public safety by restricting the freedoms of mentally ill people may not only have a minimal effect on overall violence reduction, but may also paradoxically worsen public mental health (Cole 2007).

THE SECOND AMENDMENT AND FEDERAL FIREARMS LEGISLATION

The right of citizens to bear arms was included in the Second Amendment to the U.S. Constitution in 1791. Theoretically, the Second Amendment allows people to maintain the force to organize a militia, rise up against government oppression, defend themselves and their communities, and assist in enforcing local laws. However, over 200 years later, the practical applications of Second Amendment rights have led to difficult questions. One question is who, if anyone, should be denied their Second Amendment rights. Determining who meets that threshold for dangerousness requires balancing individual freedoms with public safety.

The Gun Control Act of 1968 was the first federal statue to limit potentially dangerous individuals' access to firearms. Its inception came on the heels of the assassination of President John F. Kennedy, which raised public awareness of the relative lack of firearm regulations. The Gun Control Act specifically prohibited eight categories of people from purchasing or owning guns, including individuals legally determined to be "adjudicated as a mental defective" and those who had been "committed to any mental institution." Also prohibited were unlawful users or addicts of controlled substances, felons, fugitives from justice, individuals dishonorably discharged from the armed services, individuals who have been convicted of domestic violence or had a restraining order filed against them, people who have renounced their citizenship, and illegal aliens (Gun Control Act 1968). However, no guidance was given regarding enforcing these restrictions.

In 1981, the assassination attempt of Ronald Reagan again brought firearm regulation to the foreground. Reagan and his White House Press Secretary, James Brady, were shot and wounded by John Hinckley Jr., who later revealed that his actions were an attempt to impress the actress Jodie Foster. Though Hinckley had a history of psychiatric treatment, he had never met the criteria laid out in the Gun Control Act and was therefore able to legally obtain the gun used in the

shooting. Out of this event, the Brady Handgun Act was eventually passed in 1993, establishing a federally mandated 5-day waiting period for handgun purchases, and requiring all federally licensed dealers to perform a background check on individual purchasers to ensure that the sale would not violate federal or state law (Brady Handgun Act 1993).

The Brady Handgun Act also laid the groundwork for the eventual development of the National Instant Criminal Background Check System (NICS) in 1998. NICS is a federal database of records maintained by the Federal Bureau of Investigation (FBI). It contains information compiled from multiple sources about disqualifying criminal and mental health records of potential buyers. Federally licensed gun dealers are required to access the database prior to a transfer of a firearm to determine if the buyer meets any of the exclusionary criteria. However, nonlicensed dealers, which comprise up to 25% of sellers at gun shows, are not required to utilize the NICS background check system prior to selling guns (Brady Handgun Act 1993).

In 1997, a law enforcement officer named Printz challenged the interim provisions of the Brady Act that required law enforcement officers to enact them on a state level. In *Printz v. U.S.,* the U.S. Supreme Court decided that under the Tenth Amendment, it was unconstitutional for the federal government to require state officials to implement or enforce federal mandates. Thus, state reporting of relevant information to the federal NICS database remains voluntary, allowing large gaps in the system's data and compromising its effectiveness (Price and Norris 2010).

In 2007, Seung-Hui Cho killed 38 people on the campus of Virginia Tech before shooting himself. Two years prior to the shooting, he was found by a Virginia court to be dangerous to himself and was mandated to outpatient psychiatric treatment (*New York Times* 2007). While assisted outpatient treatment may have qualified him as "adjudicated as a mental defective," no records had been uploaded to the NICS system and Cho was able to legally purchase firearms (Price and Norris 2010).

The federal government passed the NICS Improvement Act in 2008 on the heels of the Virginia Tech shooting to assist states in communicating relevant information to the central database. It also provided financial support for records transfer, and incentives for those who maintain above a minimum level of information sharing (NICS Improvement Act 2007). However, states are only able to report to the NICS database to the level at which they themselves collect data, if they elect to report at all.

Initially, no provision existed allowing individuals disqualified on the basis of mental illness to regain their eligibility to have firearms (though this did exist for felons). This discrepancy was rectified in the 2007 NICS Improvement Act, which allowed individuals to petition for reconsideration. If the designated legal authority determines that the person is unlikely to act in a dangerous manner in the future and that his or her possession of a firearm is not contrary to public interest, that person's right to purchase and possess a firearm can be restored (NICS Improvement Act 2007).

Some confusion remained regarding the criteria for "adjudicated as a mental defective" or "committed to a mental institution." In 1997 the Bureau of Alcohol, Tobacco, Firearms, and Explosives (ATF) clarified the terms, stating that "adjudication as a mental defective" required some degree of "danger[ousness] to himself or others" or "a lack of mental capacity to contract or manage his own affairs," and included people found incompetent to stand trial or not guilty by reason of insanity. The ATF also specified that voluntary admission to a psychiatric institution or admission for observation only did not qualify for firearm purchase disqualification (ATF 1997). In 2013, an executive order further clarified that assisted or involuntary outpatient commitment qualified as "committed to a mental institution" and therefore met the criteria for firearm prohibition (Office of the Press Secretary 2014).

CASE LAW

In 1975, the District of Columbia passed a law banning ownership and registration of new nonservice handguns and requiring guns at home to be kept locked and unloaded. Heller, a law enforcement officer, sued for his right to have his service weapon at home. In *District of Columbia v. Heller* (2008), the Supreme Court struck down this law as unconstitutional. The court opined that the Second Amendment granted individuals the right to keep and bear arms, even in the home for self-defense and absent affiliation with a militia. Though the ruling upheld the prohibitions put forth in the Gun Control Act, it effectively curtailed the passage of new firearm prohibitions outside of those categories (Gould 2009).

Many other relevant cases have questioned what is meant by "committed to a mental institution" or "adjudicated as a mental defective." The groundwork for this scrutiny was laid out in the class action suit *Lessard v. Schmidt* (1972). Lessard had been detained by Wisconsin police at her home after a reported suicide attempt and was involuntarily hospitalized. Her initial detention period was extended without her knowledge, and a hearing did not take place until 24 days later. Wisconsin's commitment statutes allowed, under certain circumstances, for a patient to remain in the hospital for an "observation" period for up to 145 days without a hearing. The Wisconsin District Court found that Wisconsin's commitment procedures violated due process rights. Though the decision did not address the Second Amendment directly, it laid the groundwork for questioning the due process of involuntary commitments that would later result in firearm disqualifications (Remington 1973).

In *U.S. v. Hansel* (1972), Hansel was convicted of purchasing a firearm illegally because of his prior psychiatric hospitalization. However, the Eighth Circuit Court reversed this conviction, citing that it was not technically a "commitment" because the hospitalization was deemed to be "observational" and legal commitment procedures had not been followed. Similarly, in *U.S. v. Giardina* (1988), Giardina was hospitalized in Louisiana for 14 days, one day short of the point at which a judge's commitment order is required.

Like Hansel, his conviction for illegal firearm purchase was overturned by a court of appeals based on the lack of formal judicial commitment (Lewis 2011).

In 2012, *U.S. v. Rehlander* upheld the decision in *Hansel*. Rehlander had been hospitalized involuntarily for 5 days, but had neither an adversarial hearing nor a judicial commitment. Therefore, the First Circuit Court concluded that due process had not occurred for a formal commitment and that he did not meet the criteria for a firearm disqualification (McCreary 2013). In these cases, admission to a psychiatric hospital without a judicial commitment did not suffice to prohibit firearm purchase.

However, in both *U.S. v. Waters* and *U.S. v. Chamberlain*, the circuit courts determined that the states had followed procedure sufficiently to meet the requirements for a firearms ownership disqualification, despite the lack of an adversarial hearing and a judicial order. Waters was hospitalized in New York, where statute allowed for up to a 60-day hospitalization under the certification of two physicians and a third applicant. Waters did not request the hearing available to him during that 60 days to contest the hospitalization, then requested his status be changed to voluntary. Thus, no judicial certification took place. However, in 1994, the Second Circuit determined that formal statutory commitment requirements had been met, and that this disqualification was in line with the intentions behind the Gun Control Act: to keep guns out of the hands of potentially dangerous people with mental illness (Lewis 2011).

Chamberlain was involuntarily hospitalized on an emergency basis in Maine and, like Waters, his status changed to voluntary before the hospital had to obtain a judicial order for further commitment. The First Circuit determined in 1998 that state commitment procedures had been followed, and that his hospitalization counted as a "commitment." In *Chamberlain*, the court elaborated on the intent of the Gun Control Act, explaining that had Congress intended that a full adversarial hearing be required to merit a commitment, it would have specifically said so (Lewis 2011).

In *U.S. v. Vertz* (2000), the exclusionary criterion of "adjudicated as a mental defective" also came under scrutiny. Vertz had been treated by a variety of mental health professionals for decades, and had at one point been court-ordered to obtain outpatient treatment. He was never determined to be either dangerous or incapable of managing his own affairs, the two specific requirements for "adjudicat[ion] as a mental defective." Thus, a Michigan court ruled that he did not meet the federal standards of "mental[ly] defective" that would prohibit him from buying a gun (McCreary 2013). Of note, this ruling occurred prior to the 2013 Executive Order specifying that outpatient commitment did qualify as "committed to a mental institution."

STATE LEGISLATION

While federal legislation prohibits firearm purchase by people who have been adjudicated as mentally defective or committed to an institution, state-level legislation varies widely. Some states exclude those with any mental illness from firearm ownership, without addressing their level of dangerousness, or what, exactly, qualifies as "mental illness." Alabama and Pennsylvania prohibit firearm sales to those who are of "unsound mind." In Montana, firearm purchase can be denied to those believed with reasonable cause to be "mentally ill, defective, or disabled." In Hawaii, South Dakota, Maryland, and Oklahoma, merely being diagnosed as having a mental or behavioral disturbance suffices (Norris et al. 2006).

Other states give more concrete guidelines. In Illinois, Arkansas, and the District of Columbia, voluntary admission to a psychiatric facility triggers a prohibition. Other states, such as Kentucky, Oklahoma, and Michigan, align with the federal government and specify that this commitment must be involuntary. The federal guideline of adjudication as mentally incompetent or not guilty by reason of insanity is shared among most, but not all, states (Norris et al. 2006).

Alaska, New Hampshire, Vermont, and Colorado place virtually no restrictions on firearm purchases in cases of mental illness. Twelve other states restrict people with mental illness from obtaining a concealed weapon permit, but not from obtaining a weapon legally (Norris et al. 2006).

In California, mental health-based restrictions are more directly tied to violence potential than to psychiatric history. Admission to a psychiatric facility for danger to self or to others triggers a firearm prohibition. This differs from federal standards, by which the prohibition would not be triggered until a commitment was certified. Involuntary holds for grave disability in California (inability to provide for one's food, clothing, or shelter), by contrast, follow the federal standard (California Department of Justice 2009).

State-level prohibitions and NICS background checks prohibit the purchase or register of new guns to people with certain mental health histories or criminal records. However, they do little to remove the guns already in circulation. California, New York, Connecticut, and Indiana have developed legislation not just to prevent future firearm purchases, but to remove existing firearms during a crisis, regardless of whether or not the person has met federal or state prohibition criteria. California has also piloted a unique program to remove guns already in the possession of prohibited persons (NPR 2013).

In 1999, Connecticut became the first state to pass gun removal legislation that was based on acute potential for violence without being tied to mental illness. Under this statute, the state's attorney or two law enforcement officers can petition the courts for a warrant for gun removal from individuals perceived to pose an "imminent risk" of harm to themselves or another. Within 14 days, a hearing must occur, at which time the guns may be returned, or their removal may be authorized for 1 year (Conn. Gen. Stat. §29-38c).

In 2005, Indiana passed legislation allowing police officers to seize weapons from a person with "a propensity for violent or emotionally unstable conduct" or with mental illness, without obtaining a warrant. The legislation followed

the 2004 fatal shooting of a police officer by a man with paranoid delusions, a recent history of mental health evaluation for violence, and a large cache of weapons in his home. Though police knew he had firearms, they were unable to legally remove them at the time, because the man had never met any threshold for firearm prohibition. Interestingly, although the law was developed in response to a violent incident, the majority of the confiscations in the first two years were related to concerns for suicidality (Parker 2015).

In response to the Sandy Hook shootings in Connecticut, Governor Cuomo of New York signed the New York Secure Ammunition and Firearm Enforcement (SAFE) Act on January 15, 2013. The law prohibits possession of high-capacity magazines, tightens restrictions on gun sales, requires ammunition dealers and private firearm dealers to perform background checks, creates a registry for all semi-automatic weapons, and requires safe storage of assault weapons. Perhaps most relevant for mental health practitioners, it requires those privy to a patient's threat of violence to report that threat to the director of their facility, who in turn reports it to state authorities. Like the Indiana Dangerous Persons Law, the New York SAFE Act allows for law enforcement to remove that individual's weapons with no warrant, and without requiring other criminal or mental health history (*Huffington Post* 2013).

The 2014 Isla Vista shooting provided another situation where family members saw warning signs of violence and expressed concern to authorities. However, absent any disqualifying mental health or criminal history, police were powerless to intervene with the shooter, who had legally amassed multiple weapons. Largely in response to this event, California passed a Gun Violence Restraining Order in 2014 that was modeled closely after domestic violence restraining orders. This new law allows family members or police to petition the court when they believe there is a "substantial likelihood" that the respondent "poses a significant danger of harm to self or others in the near future by having access to a firearm." The court may then issue a warrant for gun removal with an ex-parte order, which may be converted to a 1-year order after a court hearing. Additionally, the person is prevented from owning firearms for the duration of the order via reporting to the NICS system. This legislation is another example of gun removal tied directly to acute risk of violence, rather than to mental health criteria (California Legislative Information: AB1014; Frattaroli et al. 2015).

California's Armed Prohibited Persons System (APPS) program, developed in 2007, allows the removal of weapons from prohibited persons, regardless of whether there is an elevated acute risk of violence. California Department of Justice officials cross-check disqualifying legal and psychiatric records with gun ownership records in the state firearm database. APPS agents then go to the home of firearm owners whose history prohibits ownership and confiscate any guns in their possession. In 2013, the state expanded funding for this program. A bill in Congress proposed allocating funds for other states to adopt this unique model (NPR 2013).

NICS REPORTING

The NICS database of disqualifying information is the checkpoint on which enforcement of national firearm prohibitions relies. Unfortunately, NICS is missing the names of millions of people who should be disqualified from gun ownership by their mental health or substance abuse histories (Mayors Against Illegal Guns 2011).

The efficacy of the NICS system is entirely dependent on the data supplied by individual states, which report to NICS voluntarily. As of 2012, 30 states had not uploaded any mental health records (Government Accountability Office 2012). Myriad factors contribute to this lack of participation.

Because of variations in state legislation, the disqualification data collected for transmission to NICS may not align with the federal restriction criteria. Funds provided by the NICS Improvement Act have facilitated the de-aggregation of state-level prohibitions from federal (Mayors Against Illegal Guns 2011). Other states report no information, and there is little to prevent disqualified individuals in those states from buying guns in neighboring states.

In addition, many states lack the technological infrastructure to synthesize the necessary records from law enforcement, psychiatric institutions, and courts. The NICS Improvement Act helped to address these deficiencies by providing funding and incentives to states for building functional databases that could be used for collecting and transmitting data to NICS (NICS Improvement Act 2015).

Privacy concerns are another potential barrier to NICS reporting. The Health Insurance Portability and Accountability Act (HIPAA) prohibits sharing protected patient information without permission, except under defined circumstances. Exceptions include disclosure to aid in law enforcement, protect the public against violence, and where otherwise superseded by state or federal law. Nonetheless, in 2012, officials in half the states surveyed expressed concerns about reporting patient records in the absence of a specific statute mandating reporting (Government Accountability Office 2012).

EFFECT OF NICS REPORTING ON GUN VIOLENCE

Despite attempts to address gun safety through policy changes, there have been few opportunities to examine the results. A 2000 study analyzed vital statistics of homicides and suicides by firearm before and after NICS implementation. They compared a "treatment" group of states (those who, prior to NICS, had no firearm-disqualification reporting system) and a "control" group of states (those who, prior to NICS, had an equivalent reporting system in place). They found that after the implementation of NICS, there was no difference in the change in firearm homicides and suicides between the two groups, with one notable exception: suicides by gun in people 55 and older decreased by 0.92 per 100,000 people. Additionally, this reduction was greater in states that implemented background checks and a waiting

Table 66.1 Significant U.S. firearm legislation

Year	Legislation	Content
1791	Second Amendment to the Constitution of the United States	Declares that "a well-regulated militia, being necessary to the security of a free state, the right of the people to keep and bear arms, shall not be infringed"
1968	Gun Control Act	Describes eight categories of "prohibited persons" who are not allowed to purchase or possess firearms
1993	Brady Handgun Act	Establishes waiting period for handgun purchases, required licensed dealers to perform background checks, lays groundwork for NICS
1997	*Printz v. United States*	Rules it is unconstitutional for states to be mandated to enforce federal law, effectively preventing mandatory record-sharing
1998	NICS Development	Establishes centralized database by which records of prohibited persons can be shared between states
2007	NICS Improvement Act	Incentivizes states to upload records to NICS, provides mechanism for restoration of Second Amendment rights
2008	*District of Columbia v. Heller*	Reaffirms the right of individual citizens to keep and bear arms at home in the absence of affiliation with a militia, effectively curtails future federal legislation restricting Second Amendment rights

period for gun purchase than in states that implemented background checks alone (Ludwig and Cook 2000).

Another study looked at 2002–2009 data from Connecticut to determine whether increased reporting of disqualifying mental health histories to NICS reduced gun violence. Connecticut began reporting to the NICS system in 2007. By merging data from multiple state organizations, researchers examined the incidence of gun violence and suicide in people with and without disqualifying mental health histories. The researchers reviewed records of 23,292 people with severe mental illness (defined as schizophrenia, bipolar disorder, or major depression plus at least one hospitalization). These people were categorized as having no disqualifying mental health or criminal history, having a disqualifying criminal history, or having a disqualifying mental health history. For those with a gun-disqualifying mental health history and no disqualifying criminal history, the likelihood of their committing a violent crime was reduced by 53% (6.7%–3.2%) after implementing NICS reporting. There was also a 34% decline (5.9%–3.9%) in violent crimes by people who had no disqualifying history. In contrast, those with a disqualifying criminal history were 1.6 times more likely to commit a violent crime after the 2007 reporting began. The increase in this population equalized any small reduction in overall crime contributed by the mental health disqualifications (Swanson et al. 2013).

Only 5% of people studied were disqualified from firearm purchase solely on the basis of their mental health history, and this group committed only 4% of the violent crimes in the study. Because the contribution to violent crime in this sample prior to NICS reporting was very small, even the 53% reduction in violent crime committed by this group had minimal impact on violent crime overall. In other words, even if state-level NICS reporting were done thoroughly for people with disqualifying mental health histories, and those people were successfully prohibited from purchasing firearms, the overall reduction of gun violence would likely remain small (Swanson et al. 2013). Table 66.1 summarizes significant firearm legislation in the United States.

PREVENTION STRATEGIES AND FUTURE DEVELOPMENTS

The issue of access to guns by people with real or perceived risk of violence raises the question of how to protect civil liberties while minimizing public risk. The challenge lies in determining which groups pose sufficient danger to merit targeted firearm restrictions. New policy is shifting away from focusing prohibitions on people with mental illness. Instead, groups like the Consortium for Risk-Based Firearm Policy are recommending a more evidence-based approach that looks at factors independently associated with a risk of violence. Their 2013 publication recommends increasing state-level firearm prohibitions for people who meet evidence-based criteria for an increased risk of violence, including people with substance use disorders, people with mental illness in the time period surrounding hospitalizations for violence, and people who have evoked concern for impending violence from family members or police. The report also advocates for an expansion of programs that remove firearms already in the possession of disqualified persons, and for legal mechanisms to restore Second Amendment rights after a prohibition has been triggered (Consortium for Risk-Based Firearm Policy 2013).

Finally, improved communication between states and the federal NICS database is crucial in minimizing firearm sales to potentially violent persons. Technological improvements, as well as incentives to collect and transmit more data will contribute to increased interstate communication. In order for the NICS database to be effective, gun dealers would need to be universally required to perform background checks by accessing it for every transaction. Closing

the holes that currently compromise the system will help it function more effectively to help keep firearms out of the hands of potentially dangerous people.

SUMMARY KEY POINTS

- Though the media and public often assume acts of violence, especially mass shootings, are related to mental illness, the role of mental illness in violence is small.
- Much of the federal and state legislation in the United States limiting access to firearms is tied to mental illness, and many of these laws were passed in reaction to highly publicized shootings.
- The current system to keep firearms from prohibited persons has many vulnerabilities.
- There is little evidence to show that current firearm legislation has been effective in reducing overall violence or firearm homicide, though it has likely reduced firearm suicides.
- Future legislative efforts are focusing on restricting firearm access by people at a known increased risk of violence, rather than by people with mental illness. This may not only be a more effective approach to violence prevention but may also decrease stigma of mental illness.

Women and violence

JESSICA FERRANTI

INTRODUCTION

The vast majority of the literature on violence involves acts perpetrated by men. While much has been written about violence *against* women, relatively little consideration has been given to violence perpetrated by women. Studies of violence and violence risk assessment have primarily focused on violence perpetrated by high-risk male offenders with mental health problems who end up in the forensic system. This has led to the development of violence risk assessment instruments that attempt to help identify and reduce the violence risk within forensic systems, treatment settings, and in the community. However, there has been debate about whether such studies based on male violent offender data can be extrapolated to women (Nicholls et al. 2004; Skeem et al. 2005b; Logan and Blackburn 2009; Weizmann-Henelius et al. 2010).

There is no doubt that women who commit acts of externalized violence are violating social and psychological norms more so than their male counterparts (Coontz et al. 1994). Studies have suggested that when dealing with life's stressors, provocations, and anger, women are more likely than men to use nonviolent, noncriminal, and inward coping strategies (depression, anxiety, and substance misuse) (Yourstone et al. 2008). Numerous studies have shown that the behavioral profiles associated with stress coping differ in men and women, showing higher levels of aggressive behaviors in men (Verona and Kilmer 2007; Verona et al. 2007).

Traditionally, women are seen as nurturers and men are seen as combatants. In American society, young females are routinely regarded as "less criminal" than young males, and their crimes are perceived as less serious (Freiburger 2010). However, there are now many more role models for aggression in women. Women are increasingly participating in armed forces combat on the frontlines of conflicts, movies now commonly portray female heroines who wield weapons, and female participation in aggressive contact sports such as boxing is becoming more accepted. As society evolves in its acceptance of strong females who exhibit what would traditionally be regarded as "male" traits, recent crime statistics suggest that the rate of women perpetrating violence is also increasing (Friedman et al. 2013). In 2011, U.S. law enforcement made 534,704 arrests for violent crimes; women accounted for 19.6% of the violent offenders (Federal Bureau of Investigation 2011). Although women currently account for less than 10% of the incarcerated population in the United States, the number of incarcerated women is increasing (Carson and Sabol 2012). Women are the fastest-growing segment population in jails and prisons.

Studies suggest that regarding gender differences in violence risk, mental illness may substantially shift the balance in the direction of gender parity. Recent literature on risk of violence in mentally ill individuals indicates that women with mental illness have the potential to be as violent as mentally ill males (Maden 2007). Hodgins (1992) found that women with a major mental disorder were about 27 times more likely than non-mentally ill women to be convicted of a violent crime.

Studies suggest that clinicians are limited in their ability to accurately assess female patients' violence risk and tend to underestimate the level of risk in women (Skeem et al. 2005a,b). Some research suggests that women with psychiatric problems may display different biopsychosocial risk factors and antecedents compared to men. The motivation for most violence perpetrated by women seemingly differs in typology. (See Table 67.1).

TYPOLOGY OF VIOLENCE AND GENDER DIFFERENCES

Barratt et al. (1991) established a classification of aggression in humans: medically related (i.e., psychotic) aggression; premeditated (predatory) aggression; and impulsive (reactive or affective) aggression. Studies have consistently shown that accurate characterization of aggressive acts helps clinicians understand, treat, and prevent violence (Nolan et al. 2003; Quanbeck et al. 2007). Women tend to engage primarily in acts of impulsive violence and psychotic aggression (Krakowski and Czobor 2004). Women commit acts of

Table 67.1 Gender differences in typology of violence and victim characteristics

	Men	Women
Type of violence	Primarily impulsive, some predatory, some psychotic	Primarily impulsive, some psychotic, less frequent predatory/premeditated
Adult victims	Victims are usually known; vast majority of stranger violence carried out by men	Typically a family member or close social contact; extremely rarely engage in stranger violence
Child victims	Victims are most often adults	Victims are most often children
Site of violence	Often outside of the home	Most often in the home

premeditated or predatory aggression much less commonly than men (Frei et al. 2006; Katsavdakis et al. 2011). Women commit very few acts of violence toward strangers or against individuals whom they do not know within the social fabric of their lives (Harrell 2012).

IMPULSIVE VIOLENCE

Studies indicate that impulsive violence is often the result of interpersonal conflict within the social framework of the woman's life, including parents, husbands, and romantic partners, as well as children (Monahan and MacArthur Violence Risk Assessment Study 2001; Weizmann-Henelius et al. 2003; Yourstone et al. 2008). Compared to men, women are more likely to commit impulsive violent crimes at home (Meloy 2006).

Intimate partner violence

Women are far more often victims of intimate partner violence than perpetrators. While the physical and other power disparities between men and women are incontrovertible, studies have reported that both sexes admit to using violence against their partners (Frieze 2005). Women who are battered within relationships may use violence to defend themselves, to express anger, or to retaliate, but they are significantly more likely than men to sustain serious injuries from the ensuing violence (McHugh and Frieze 2006). Although alcohol use has been found to be a consistent risk factor for violence by men toward a female partner (Watkins et al. 2014), the same has not been clearly shown in violence by women toward their partners (Cunradi et al. 1999; Cogan and Ballinger 2006; Cunradi et al. 2011). Personality traits in the antisocial, borderline, and narcissistic domains occur at higher rates in male batterers (Fernandez-Montalvo and Echeburua 2008). These Cluster B personality traits that are characterized by poor frustration tolerance, instability of affect, aggressiveness, and impulsivity, are also pervasive in women who commit acts of interpersonal violence (Ross 2011; Maneta et al. 2013; Sijtsema et al. 2014).

Violence by women against children

The victims of violence perpetrated by women are most often children. Women who engage in impulsive physical maltreatment of their children often have higher rates of substance misuse and depression (Chemtob et al. 2013; Easterbrooks et al. 2013). Once again, Cluster B personality traits increase risk. Some studies indicate that women who are physically violent toward children have often been victims of physical abuse (Lang et al. 2006; Chemtob et al. 2013). Mothers who react to their children with violence tend to be overly reactive to their children's misbehavior (Bradley and Peters 1991; Caselles and Milner 2000). In one study of a nonpsychiatric population, 70% of mothers of colicky infants had explicit aggressive thoughts toward their infants, and 26% of these mothers had infanticidal thoughts (Levitzky and Cooper 2000).

Stranger violence

Impulsive violence by women against strangers is rare. In crimes against strangers by women, the perpetrators often have substance use problems, psychosis, and/or personality disorders. Impulsive violence by women against strangers may also spontaneously occur in the commission of other crimes.

Female gangs

For females with socioeconomic hardships and dysfunctional homes, gang membership has increasingly become an option. Traditionally, females involved in gangs were seen as ancillary associates of male groups and were defined by their relation to male members (Molidor 1996). Today, females are increasingly involved in gangs in one of three ways:

1. Membership in an independent female gang
2. Membership in a male gang as an ancillary member
3. Membership in a female offshoot of a male gang

Most researchers estimate that about 10% of all gang members are female (Hess et al. 2013). Physical fighting with peers to secure territory and resolve disputes with rival gangs makes violence directed toward strangers far more common in young females who are involved in gangs (Wingood et al. 2002).

PSYCHOTIC VIOLENCE

The risk of violence that is motivated by psychosis in women is associated with personality disorders (antisocial and borderline prominently), substance use disorders, psychiatric medication noncompliance, and poor clinical status/active

symptoms (Dean et al. 2006). There is growing evidence that psychosis, especially delusional thinking, confers a disproportionate risk of violence on women compared to men (Hodgins et al. 1996; Dean et al. 2006). However, the association between certain types of psychotic symptoms and violence in both sexes is not entirely clear. Some studies have found that delusions are associated with serious violence (Humphreys and Johnstone 1993), while other studies have failed to find a clear association between delusions and violence (Teplin et al. 1994; Appelbaum et al. 2000; Stompe et al. 2004). There is some evidence of special patterns in the relationship between psychosis and violence in women. Because delusions are expressed through the filter of an individual's psychosocial experience and psychology, women suffering from psychosis may exhibit gender differences in the thematic content of their psychotic symptoms. In a study comparing 47 male and female homicide offenders found not guilty by reason of insanity (NGRI), Ferranti et al. (2013) reported that religious delusions were more common in female homicide offenders who killed infants and children. In addition, the male homicide offenders did not have any victims under the age of 18, and religious delusions were less frequently present, regardless of the victim's age. These results were consistent with other recent research on child murder by female homicide offenders found NGRI. In a study of women found NGRI for filicide, Friedman et al. (2005) found that the women frequently had mood problems, experienced auditory hallucinations, and almost all perpetrators had altruistic or acutely psychotic (delusional) motives.

Women who are motivated to violence by religious delusions often have self-preservation or the altruistic preservation of their children as the goal. Altruistically motivated filicide has been described by Resnick (1969) in his seminal work on motives in women who kill their children. The finding that many female perpetrators of psychotically motivated homicide against children have been found to have religious delusions at the time of the homicide is a red flag for clinicians who are evaluating women at risk of engaging in violence against their children. The presence of a psychotic disorder in women, particularly when paired with personality disorders and traits that confer high aggressivity, fearlessness, and externalized behaviors, is a mental health constellation that warrants a high degree of clinical surveillance for violence risk.

PREDATORY FEMALE OFFENDERS

Compared to men, acts of predatory violence by women are rare (Maden 2007). As with men, women who commit acts of predatory violence do so when motivated by an external goal, i.e., the intention to do the violence as revenge, primitive drive (aggressive or sexual) gratification, as an instrumental action to achieve personal or political profit, or to facilitate some other criminal intent such as robbery. Table 67.2 summarizes differences between men and woman in predatory homicides.

Table 67.2 Gender differences in predatory serial killing and mass murder

	Men	Women
Most common motivation for serial killing	Sadistic pleasure, sexual gratification	Personal profit
Victims	Strangers	Individuals within social environment
Method	Blunt force, use of sharp weapons	Most commonly poisoning
Mass murder	Men with firearm (more than 90% of all U.S. reported cases)	Very rarely commit mass murder (less than 10% of all U.S. reported cases)

SERIAL MURDER

Serial murder is rare in general, and serial murder by women is extremely infrequent. Hickey (1997) analyzed 35 cases of female serial killers in the United States who were active between 1795 and 1988. In about 75% of the cases, personal profit was seemingly the motive. In contrast, male perpetrators of serial killings commonly had sadistic and/or sexual gratification as primary motives (Frei et al. 2006). Of female serial killers, poisoning was the most common method of killing, and women primarily killed people they knew (Hickey 1997). In another study reporting on 105 female serial killers in 18 countries, poisoning was also the most common method of killing (Wilson and Hilton 1998). The findings that women tend to use more covert methods of killing, target individuals within their social environment, and exhibit less sadistic gratification in the killings are all important gender differences in serial murder.

MASS MURDER

Based on criminal databases, 72 mass murders occurred between 2000 and 2012 in the United States and 94% of the perpetrators were male (Federal Bureau of Investigation 2014). Choice of weapon may be factor as women appear less likely to use firearms in homicidal acts and are more likely to use knives, poisoning, or other methods that make killing multiple people at one time unfeasible (Wilson and Hilton 1998; Ferranti et al. 2013). In a series of two articles, Knoll discusses the militaristic nature of some mass murders using the term "pseudocommando" (Dietz 1986) to describe a type of offender who attacks in broad daylight, plans the attack, and carries out the offense with a large arsenal of weapons (Dietz 1986; Knoll 2010a,b). Knoll discusses the psychology of revenge and the "warrior" archetype (Knoll 2010a).

Traditional gender roles have dictated that, in times of military conflict, women's involvement in U.S. military forces centered on caretaking tasks such as nursing and cooking. In our history, women have only recently begun to have a role as "warriors" in contemporary armed forces combat. It is anticipated that women will be increasingly engaging in direct combat in positions on the frontlines of the armed forces. Once again, society's shifting conceptualization of gender roles and changing social conditioning of females may be an important influence in increasing the prevalence of violence perpetrated by women.

FILICIDE

Children are most often the victims of lethal violence perpetrated by women. In his review of the world literature on filicide, Resnick (1969) identified five major motives of maternal filicide:

1. Altruistic
2. Acutely psychotic
3. Fatal maltreatment
4. Unwanted child filicide
5. Spouse revenge filicide

In an altruistic filicide, a mother kills her child out of love, believing death to be in the child's best interest. In an acutely psychotic filicide, a psychotic or delirious mother can kill her child without any comprehensible motive as a result of disorganized behaviors or as a result of following command hallucinations. In mothers who physically abuse their children, fatal maltreatment filicide occurs, but murder is neither the intention of the act nor the anticipated outcome. In unwanted child filicide, a mother kills a child who is not wanted. Spouse revenge filicide is the rarest classification of filicide, and it occurs when a mother kills her child to inflict punishment via emotional harm to the child's father.

In studies looking at serious maternal violence against children, the risk of a fatality from maternal child abuse increases substantially when the mother has a major psychiatric illness (Husain and Daniel 1984; Friedman et al. 2005; Friedman and Resnick 2011). The filicide risk increases relative to other psychiatric disorders for children whose mothers have schizophrenia or mood disorders (Friedman and Resnick 2011). Based on U.S. Bureau of Justice Statistics reporting on homicide trends in the United States between 1980 and 2008, for children under the age of 5 killed by a parent, the homicide rate for biological fathers was only slightly higher than for biological mothers (Cooper and Smith 2011). However, of children under the age of 5 killed by someone other than their parent, 80% were killed by males (Cooper and Smith 2011).

POSTPARTUM VIOLENCE

Postpartum problems are generally categorized into two major categories: postpartum depression (including the less severe "baby blues") and postpartum psychosis. Studies have indicated that milder depressive symptoms, aka "baby blues," occur in as many as 70% of new mothers (Halbreich 2005). Major depressive disorder affects about 15% of new mothers (Friedman and Resnick 2009b). Women in situations of intimate partner violence have increased rates of postpartum depression (Lobato et al. 2012). In homes with intimate partner violence, there is a powerful confluence of risk factors for violence toward infants, including a climate of externalized violence as a means of resolving conflict.

Postpartum psychosis is the most severe postpartum mental disorder. Postpartum psychosis occurs in about 1–2 per 1000 childbirths (Spinelli 2009). The rate is 100 times higher in women with bipolar disorder or a past history of postpartum psychosis (Spinelli 2009). The psychotic symptoms typically present in the first 3–14 days postpartum, although some women may present several months later, usually with psychotic depression (Rhode and Marneros 1993). Women with postpartum psychosis are more likely to commit acts of violence toward themselves and to commit infanticide.

In 1970, Resnick coined the term "neonaticide" to denote the murder of a child within the first 24 hours of life, the period of highest risk for maternal violence (Resnick 1970). Almost all neonaticides are committed by women (Friedman and Resnick 2009a). Mothers who commit filicide are more frequently married compared with mothers who commit neonaticide. They also have a high frequency of substance use, unemployment, and a personal history of being abused (Friedman et al. 2005).

VIOLENCE RISK FACTOR PROFILES IN WOMEN

Psychosocial factors

Negative family environment, physical abuse, sexual abuse, and neglect by early caretakers are factors common in women who commit violent acts (Molidor 1996; Dean et al. 2006; Yourstone et al. 2008; Taylor and Bragado-Jimenez 2009; Ferranti et al. 2013; Tripodi and Pettus-Davis 2013). Maternal neglect in particular has been shown to be especially harmful to girls' development. In one study by Raine et al. (1994), maternal rejection at age 1 was shown to predict violent crime at age 18. Psychiatric illness is common in the parents of violent females (Yourstone et al. 2008). Violent parental modeling in the home, including exposure to intimate partner violence, contributes to intergenerational transmission of antisocial behavior in both males and females (Logan et al. 2009; Ehrensaft and Cohen 2012). Compared with men, women are more commonly married, living with an intimate partner, and/or have children at the time of the violent act (Table 67.3). While close social infrastructure is a protective factor for men, in women it is associated with a heightened risk of violence. The victims of women are

Table 67.3 Gender differences in violence risk profiles of violent offenders

	Men	Women
Social structure	Less commonly married or partnered	Commonly married or partnered and have children
Past history of violence	Often have past history of violence	Lethal act may be first and only crime
Juvenile history	May have a history of Conduct Disorder, juvenile offenses	Less commonly have juvenile offense history
Criminal history	May have longitudinal history of criminality	Less commonly have history of criminality
Mental illness	May or may not have mental illness; in psychiatric inpatient populations may commit violent acts at rate *equal* to women	May or may not have mental illness; however, 27 times more likely to commit a violent act if mental illness is present; violence rates for men and women in inpatient psychiatric populations have often been shown to be *equal*
Substance use disorder	Associated with violence	Associated with violence; impulsive violence against strangers more likely with alcohol intoxication
Personality disorder	More likely to have antisocial personality disorder diagnosis; commonly score higher on psychopathy measures	More likely to have borderline personality disorder diagnosis; commonly score lower on psychopathy measures

typically close to them, both in social relationship and in environmental proximity.

Every clinician learns the mantra that the best predictor of future violence is a history of violence. However, research suggests that there may be important exceptions in women. Some studies have shown that for women who have committed extreme acts of violence, i.e., homicide, the lethal act of violence was commonly their first and only crime (Yourstone et al. 2008; Ferranti et al. 2013). In women with major mental illness, violent recidivism rates are similar to cases of violent men with mental illness (Eronen et al. 1996; Putkonen et al. 2003).

Juvenile history

Conduct disorder in childhood is known to be a pathway to adult violent offending. For women, the lack of juvenile and longitudinal criminality may contribute to lower scores on measures of psychopathy such as the Hare Psychopathy Checklist-Revised (PCL-R), which may lead to underestimation of violence risk when utilizing structured violence risk assessment instruments. Psychiatric disorders appear to weigh more heavily in the violence risk potential of women. Societal perceptions of girls' aberrant behavior as less threatening than boys' behaviors may contribute to girls falling below the detection of law enforcement. Gender differences in delinquency risk factors have been observed. Early onset of puberty, sexual abuse, and problems with depression and anxiety had a higher correlation with delinquency in girls (Zahn et al. 2008). Rhoades and colleagues (2015) found that for men, involvement in the juvenile justice system alone predicted risk of adult arrest; however, for women, juvenile justice system referral was not a significant predictor of adult arrest. Instead, for women, family violence, parental divorce, and cumulative childhood risk factors were significant predictors of adult arrest.

Mental disorder

Studies consistently demonstrate high rates of psychiatric illness in women who are violent (Teplin et al. 1996; Robbins et al. 2003; Nicholls et al. 2009; Taylor and Bragado-Jimenez 2009). Substance use disorders and posttraumatic stress disorder (PTSD) are highly prevalent in population samples of incarcerated women (Wolff et al. 2011; Tripodi and Pettus-Davis 2013; Lynch et al. 2014). Studies indicate that there is a high prevalence of PTSD in women who commit violent crimes, supporting the association between the victimization of females and later perpetration of violence (Teplin et al. 1996).

In psychiatric inpatients, the risk of violence for men and women has been reported as equal in multiple studies (Binder and McNiel 1990; Lam et al. 2000; Robbins et al. 2003; Krakowski and Czobor 2004; Skeem et al. 2005b). When inpatient violence does occur, men commit more acts of violence that lead to serious injuries (Lam et al. 2000; Krakowski and Czobor 2004). In the general population being male *is* one of the most important static risk factors for violence, but once the parameters change to the acute inpatient psychiatric population, female patients can be equally violent. This relative absence of core gender differences in inpatient psychiatric populations has also been shown in forensic inpatients (Robbins et al. 2003; Nicholls et al. 2009). However, a 2015 meta-analysis investigating factors associated with violence by psychiatric inpatients found that studies with higher proportions of male patients reported higher rates of violence (Iozzino et al. 2015).

Borderline personality disorder

Borderline personality disorder is most correlated with externalized and self-directed violence in women (Logan and Blackburn 2009). Logan et al. (2009) reported that women incarcerated for a major violent offense were four times more likely to have a diagnosis of borderline personality disorder. Kuo and Linehan (2009) investigated biologic vulnerability to high emotional reactivity in individuals with borderline personality disorder and found higher reactivity to evocative stimuli. The tendency to form unstable and/or chaotic emotional attachments with others may help account for the frequency of violence in women with borderline personality disorder.

Antisocial personality disorder and psychopathy

Research suggests that the rate of antisocial personality disorder is lower in women compared to men across a range of institutional, forensic, and community settings (Dolan and Vollm 2009). In community samples, twofold to fivefold higher rates of antisocial personality disorder are typically found in men. Violent women are more likely to have been given a diagnosis of a mood disorder or borderline personality disorder and are less likely to have been given a diagnosis of conduct disorder or antisocial personality disorder (Rutherford et al. 1995; Beck 2004; Weizmann-Henelius et al. 2010; Ferranti et al. 2013).

Whether the diagnosis of borderline personality disorder and the psychopathy construct contain gender biases is an important question to consider. There may be sociological biases that cause mental health practitioners to more readily view affective dyscontrol problems as "female" disorders and more readily define antisocial tendencies as synonymous with a criminality. Research on psychopathy is often conducted on incarcerated populations; however, there are gender biases in sentencing that lead to fewer incarcerated female psychopathic individuals than male psychopathic individuals (Freiburger 2010).

Substance use and violence

Studies of violent female offenders have shown a strong association with substance use disorders (Sacks 2004). Alcohol, methamphetamine, and cocaine are the most commonly abused substances by women who commit acts of violence. In a study by Collins et al. (2007), women who committed acts of impulsive violence in bars most commonly did so against strangers. Acts of violence by women against strangers are exceedingly rare, but it appears that the social environment and the consumption of alcohol were able to override the typical patterns of violence by women. When the violence was directed at a stranger in the bar, the opponent was most often another woman of similar age, height, and physical build. The investigators found that the major precipitants of the incidents were predominantly either perceptions of obnoxious behavior or a conflict over a romantic partner. The women reported high alcohol intake before the incidents. The number of drinks consumed in the bar prior to the incident was positively correlated to violent acts. The authors concluded that the act of stranger violence was perhaps related to the gender and physical match between perpetrator and opponent. This finding has interesting implications for an evolutionary model for women's violence against other women in social settings, which may spur competitiveness for traditional resources such as environmental space and romantic partners.

Some studies suggest important gender differences in the association of aggressive responding with alcohol use. Alcohol use has been found to be a consistent risk factor for violence by men toward a female partner (Watkins et al. 2014). However, alcohol has not been clearly shown as a risk factor for violence by women toward a male partner (Cunradi et al. 1999; Cogan and Ballinger 2006; Cunradi et al. 2011).

SUMMARY

Although much has been written about violence perpetrated by men, relatively little consideration has been given to violence perpetrated by women. Research in the area of women and violence is growing and yielding important information about gender differences. The recent literature on violence indicates that certain populations of women with mental illness have the potential to be equally as violent as their male counterparts. These data offer an opportunity for improved interventions and treatment for women at risk.

SUMMARY KEY POINTS

- The criminal and psychological variables of violent women are often different than violent men.
- Women with mental illness may have the potential to be equally as violent as men with mental illness.
- Children are most often the victims of violence perpetrated by women.
- Women may score lower on structured violence risk assessment instruments.
- Being aware of gender differences in the risk factor profiles of women is essential to accurate detection and prevention of violence.

Use of psychological assessment tools in forensic psychiatric evaluation

SANJAY SHAH AND RANDY K. OTTO

INTRODUCTION

Forensic examination by psychiatrists and psychologists is predicated upon the assumption that, because of their expertise, these mental health professionals can provide the legal decision maker with information about the examinee's psychiatric and psychological functioning that are relevant to some legal issue in dispute, resulting in more informed, and presumably more accurate, decisions. Thus, the goal of forensic psychiatric assessment and forensic psychological examination is to assess and describe those aspects of the examinee's emotional, behavioral, and/or cognitive functioning that are relevant to some legal issue in dispute. Of course, forensic psychiatrists and forensic psychologists can only provide legal decision makers with helpful information if they employ valid assessment techniques. In this chapter we discuss the potential value of psychological assessment tools in a forensic psychiatric evaluation.

A MODEL FOR FORENSIC ASSESSMENT

Grisso (1986, 2003) proposed a model for forensic mental health assessment that can be applied to essentially any legal matter in which questions about an individual's emotional, behavioral, or cognitive functioning are at issue (see Figure 68.1). First, the examiner must be familiar with the relevant law. Thus, if evaluating a criminal defendant whose competence to stand trial is in dispute, the examiner must know what the law requires of a defendant when participating in the legal process. Next, the examiner distills from this what legal matters may be impacted by the examinee's emotional, behavioral, and/or cognitive functioning. By doing this, the examiner identifies the "psycholegal capacities" of relevance. In the case of a criminal defendant whose competence to stand trial is in dispute, the examiner would assess the defendant's emotional, behavioral, or cognitive functioning and how it affected his or her rational and factual understanding of the legal proceedings, and his or her ability to consult with counsel (*Dusky v. U.S.* 1960). Finally, the examiner selects the assessment techniques that best aid in assessment of these identified psycholegal capacities. Figure 68.1 provides a model for the forensic mental health evaluation.

DISTINGUISHING BETWEEN DIFFERENT TYPES OF ASSESSMENT TOOLS

There is no clear definition of what is meant by a psychiatric or psychological test. The *Standards for Educational and Psychological Testing* (Joint Committee on the Standards for Educational and Psychological Testing of the American Educational Research Association, the American Psychological Association, and the National Council on Measurement in Education 2014; hereinafter Joint Committee 2014) notes, "A test is a device or evaluative procedure in which a sample of an examinee's behavior in a specified domain is obtained and subsequently evaluated and scored using a standardized process. Whereas the label *test* is sometimes reserved for instruments on which responses are evaluated for their correctness or quality, and the terms *scale* and *inventory* are used for measures of attitudes, interest, and dispositions, the *Standards* uses the single term tests to refer to all such evaluative devices…[T]ests standardize the process by which test takers' responses to test materials are evaluated and scored" (Joint Committee 2014, 2, emphasis in original).

In this chapter we consider psychiatric and psychological assessment techniques broadly. The assessment tools psychiatrists and psychologists use can be categorized with respect to the constructs they assess and how they perform.

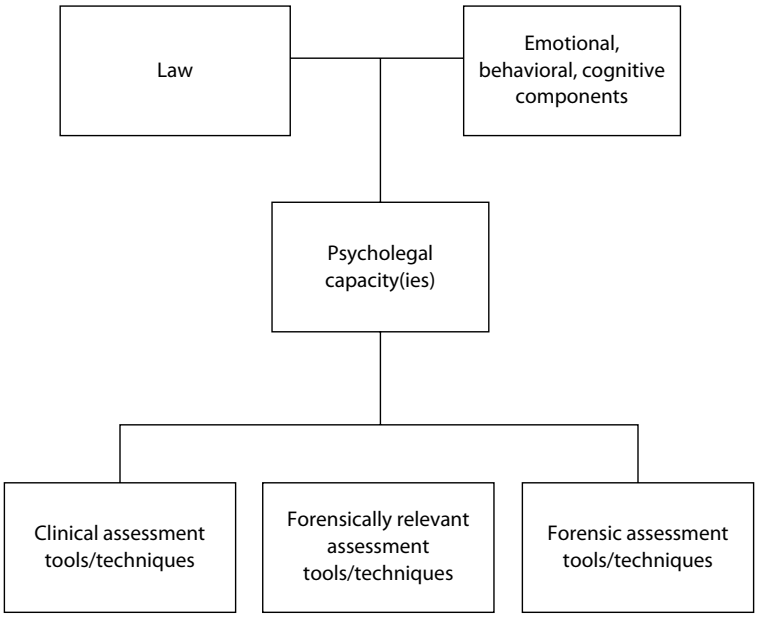

Figure 68.1 A model for forensic mental health evaluation. (Adapted from Grisso T. 1986. *Evaluating Competencies: Forensic Assessments and Instruments*. New York: Plenum Press.)

CLASSIFYING ASSESSMENT TOOLS ACCORDING TO THE CONSTRUCTS THEY ASSESS

Clinical assessment techniques

When conducting forensic evaluations psychiatrists typically employ assessment techniques that they also rely on when providing therapeutic services (e.g., the clinical interview; tests that aid in assessment of central nervous system structure, functioning, and metabolism such as magnetic resonance imaging [MRI], positron emission tomography [PET], and electroencephalogram; and tests that aid in assessment of more general health and functioning such as blood panels). Similarly, when conducting forensic evaluations psychologists often employ many of the same assessment tools they use in therapeutic settings (e.g., clinical interview, measures of emotional and behavioral functioning such as the Minnesota Multiphasic Personality Inventory-2 Restructured Form [MMPI-2-RF], measures of intellectual functioning such as the Wechsler Adult Intelligence Scale-4th edition [WAIS-IV]). All of these assessment tools, only some of which are "tests," can be classified as clinical assessment techniques (CATs) insofar as they assess clinical constructs or phenomena. Heilbrun, Rogers, and Otto (2002), in their discussion of assessment techniques that are employed in forensic psychiatric and psychological evaluations, distinguished these tools from two other types—forensically relevant assessment techniques (FRATs) and forensic assessment techniques (FATs).

Most CATs employed by psychiatrists and psychologists assess constructs that are fairly far removed from the questions the legal decision maker has about an examinee's functioning (see Table 68.1). For example, results of brain magnetic resonance imaging or the WAIS-IV provide little information about a defendant's understanding of the legal process and capacity to work with counsel, and results of a PET scan or the MMPI-2-RF tell us little about the likelihood the examinee will engage in violent behavior if her civil commitment is terminated. These measures are not without any value, however. Rather, they can be quite helpful with respect to identifying and/or describing clinical conditions underlying observed deficits in psycholegal capacities. Thus, results of MRI or the WAIS-IV may assist in identifying *why* a defendant demonstrates a limited understanding of the legal process and compromised ability to consult with his attorney. Similarly, results of PET and the MMPI-2-RF may identify clinical conditions that are associated with an increased risk for violent behavior in the community. Noteworthy is that the most commonly employed CAT—the clinical interview—not only assists in assessment of an examinee's general emotional, behavioral, and cognitive functioning, but it can also be tailored to focus on psycholegal abilities such as a defendant's mental state at the time of the offense or a child's understanding of the oath and need to tell the truth when testifying.

Forensically relevant assessment techniques

Like CATs, FRATs aid in assessment of clinical constructs, but clinical constructs that typically are of more relevance or interest in forensic contexts or settings. Thus, assessment tools that inform or structure judgments about risk for violence (e.g., Historical Clinical Risk Management-20, Version 3 [HCR-20]), response style (e.g., Word Memory Test [WMT]), and psychopathy (e.g., Psychopathy Checklist-Revised) are

Table 68.1 Examples of clinical assessment tools

	Norm based	Structured professional judgment	Checklist/ criterion referenced	Construct examined
Medical				
Clinical interview				Relevant history and functioning
Magnetic resonance imaging	✓			Measure of structure
Electroencephalograph	✓			Brain function
Blood panels	✓			Metabolism
Psychological				
Clinical interview				Relevant history and functioning
Millon Clinical Multiaxial Inventory-III (MCMI-III)	✓			Psychopathology and personality
Minnesota Multiphasic Personality Inventory-2-Restructured Form (MMPI-2-RF)	✓			Psychopathology and personality
Personality Assessment Inventory (PAI)	✓			Psychopathology and personality
Wechsler Adult Intelligence Scale-4th edition (WAIS-IV)	✓			Intelligence
Adaptive Behavior Assessment System-II (ABAS-II)	✓			Adaptive behavior
Wechsler Memory Scale-IV (WMS-IV)	✓			Memory functions
Wide Range Achievement Test 4 (WRAT4)	✓			Academic achievement
Folstein Mini-Mental State Examination	✓			Cognitive functioning

considered FRATs (see Table 68.2). Examples of forensically relevant assessment tools are provided in Table 68.2.

Forensic assessment techniques

In contrast to CATs and FRATs, FATs are specifically developed to aid in assessment of psycholegal capacities. Thus, tools specifically designed to structure or inform judgments about psycholegal capacities such as trial competence (e.g., MacArthur Competence Assessment Tool–Criminal Adjudication [MacCAT-CA]), mental state at the time of the offense (e.g., Roger's Criminal Responsibility Assessment Scales [R-CRAS]), and capacity to make treatment decisions (e.g., MacArthur Competence Assessment Tool–Treatment [MacCAT-T]) qualify as FATs (see Table 68.3). Of some historical interest is that one of the first FATs—a checklist

Table 68.2 Examples of forensically relevant assessment tools

	Norm based	Structured professional judgment	Checklist/ criterion referenced	Construct measured
Inventory of Legal Knowledge (ILK)	✓			Response style
Miller Forensic Assessment of Symptoms Test (M-FAST)	✓			Response style
Test of Memory Malingering (TOMM)	✓			Response style
Level of Service Inventory-Revised (LSI-R)	✓			Offense risk and intervention needs
Historical Clinical Risk Managment-20 (HCR-20)		✓		Violence risk
Violence Risk Appraisal Guide (VRAG)	✓			Violence risk
Structured Assessment of Violence Risk in Youth (SAVRY)		✓		Violence risk
Psychopathy Checklist-Revised (PCL-R)	✓			Psychopathy
Static-99	✓			Sex offender recidivism risk
Sexual Violence Risk-20 (SVR-20)		✓		Sexual offense risk
Spousal Assault Risk Assessment (SARA)		✓		Spousal assault risk

Table 68.3 Examples of forensic assessment tools

	Norm based	Structured professional judgment	Checklist/ criterion referenced	Construct measured
Evaluation of Competency to Stand Trial-Revised (ECST-R)	✓			Competency to stand trial
Fitness Interview Test-Revised (FIT-R)		✓		Competency to stand trial
MacArthur Competence Assessment Tool–Criminal Adjudication (MacCAT-CA)	✓			Competency to stand trial
Rogers' Criminal Responsibility Assessment Scales (R-CRAS)	✓			Criminal responsibility
Static-99/Static-2002	✓			Sex offender recidivism risk
Instruments for Assessing, Understanding, and Appreciating *Miranda* Rights	✓			*Miranda* rights comprehension

designed to structure assessments about criminal defendants' competence to proceed with the legal process—was developed by a psychiatrist, Robey (1965).

Comparing CATs, FRATs, and FATs

Generally speaking, the best validated assessment techniques are CATs, followed by FRATs and FATs (Heilbrun et al. 2002). Because of their broader application, most CATs like the WAIS-IV, MMPI-2-RF, and PAI, have larger normative samples and greater research bases examining their reliability and validity than more focused assessment tools. This presents forensic examiners with an interesting challenge insofar as the best validated tools examine constructs that are most removed from the psycholegal capacities about which the legal decision maker is concerned and the forensic examiner is attempting to assess.

CLASSIFYING ASSESSMENT TOOLS ACCORDING TO HOW THEY FUNCTION

Another way that assessment tools can be classified is with respect to how they function.

Norm-based assessment tools (tests)

Many assessment tools that psychiatrists and psychologists employ gain their utility because they provide normative data about examinees. The rationale underlying and value of norm-based assessment techniques—which are typically described as tests—are the same, whether they are medical tests such as MRI or psychological tests such as the WAIS-IV. The examiner draws conclusions about an examinee based on how his or her performance compares to a relevant comparison or norm group. Thus, the psychiatrist reviewing results of a brain image forms opinions about the examinee's brain functioning based on how the size of her ventricles compare to some normative comparison group. Similarly, the psychologist reviewing results of the WAIS-IV forms opinions about the examinee's intellectual and cognitive functioning by comparing his or her performance to same-aged peers on which the test was normed.

Although many CATs gain their utility from their norms-based approach, some FRATs and FATS provide such data as well. For example, the Psychopathy Checklist-Revised (PCL-R), a FRAT, informs an examiner's judgments about the psychopathic personality traits of an examinee by comparing the examiner's ratings of the examinee on 20 different items to the ratings of persons in various normative groups, including prison and forensic hospital samples. Similarly, the MacCAT-CA provides normative data about a criminal defendant's understanding of and ability to participate in the legal process by comparing his or her scores on the measure to the scores of various normative groups including defendants who were adjudicated incompetent to proceed, defendants with mental disorders for whom competence to proceed was not an issue, and defendants without any indications of mental disorder.

Structured professional judgment tools

Structured professional judgment tools (SPJTs) ensure a comprehensive assessment of factors that are relevant to understanding the phenomenon or construct of interest. They are not tests but are best conceptualized as checklists or memory aids that ensure consideration of all factors that are important when trying to understand a particular matter. SPJTs are typically developed by reviewing the empirical literature devoted to a topic area, and identifying those factors that should be considered when making decisions about the matter. For example, the HCR-20 is a SPJT that structures inquiries and judgments about violence risk for persons with mental disorders. Use of the tool involves conducting a clinical evaluation that is sure to consider the 20 items/factors the instrument authors determined were related to violence risk in this population based on their review of the literature (e.g., history of violent behavior, substance use, attitudes toward treatment). Similarly, the Fitness Interview Test–Revised (FIT-R), a SPJT designed

for use when evaluating criminal defendants' competence to proceed with the legal process, requires the examiner to address 16 areas the instrument authors determined to be relevant to considering a defendant's understanding of and ability to participate in the legal process (e.g., understanding the nature and severity of the charge, appraisal of likely outcomes, capacity to relate to lawyer, capacity to plan legal strategy). In contrast to the HCR-20, however, in additional to considering the psychiatry and psychology literatures regarding trial competence, the FIT-R authors also considered statutes and case law that shape the legal construct of competence to proceed with the legal process.

SPJTs typically replace unstructured clinical judgment that, at least historically, describes much of what psychiatrists and psychologists have done in therapeutic and forensic settings. As compared to unstructured clinical judgment, professional judgments that are structured by empirically and/or legally grounded tools are more reliable and valid. As a result, there has been a clear movement to this approach in both medicine and psychology.

Actuarial assessment tools

A little more than a half-century ago Meehl (1954) published his treatise on the value of actuarial classification and assessment approaches. The actuarial method "uses an equation, formula or graph, or an actuarial table to arrive at a probability, or expected value, of some outcome" (Grove and Meehl 1996, 294). Actuarial assessment involves the mechanistic combination of select variables to classify or predict.

When actuarial assessment is discussed, it is routinely assumed that the variables that are included in the actuarial formula are derived empirically. However, strictly speaking, this need not be the case. Thus, one could describe the diagnostic approach employed in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*; American Psychiatric Association 2013) as an actuarial one insofar as examinees are determined to have or not have a particular disorder based on what and how many diagnostic criteria (i.e., signs and symptoms) are observed. Typically, however, the items used to classify or predict are derived empirically, and the weight or significance assigned to any item is determined empirically as well. As an example, in their development of the Violence Risk Appraisal Guide (VRAG), Quinsey and his colleagues (1998) compared two groups of male incarcerated offenders in Canada who had been released to the community and followed for a number of years, some of whom were rearrested for a violent offense, and some of whom were not. Upon comparing the two groups on a large number of variables the investigators identified 12 that differentiated them (e.g., elementary school problems, history of alcohol abuse, level of psychopathy, age at time of index offense, marital history, criminal history). Finally, the investigators developed a formula in which the 12 items were weighted so as to maximally separate the two groups of offenders. They subsequently proposed that mental health and correctional professionals faced with making judgments about offenders' risk for violent reoffending use this tool.

As suggested by the above discussion of the VRAG, actuarial assessment is typically considered in the context of prediction in mental health applications (e.g., predicting whether someone will reoffend, abuse her child, or attempt suicide). However, it can be used for nonpredictive purposes as well. For example, the Rogers Discriminant Function and the Cashel Index are two actuarial formulas within the Personality Assessment Inventory (PAI) that are not used for prediction but are used to identify whether the examinee was feigning impairment when responding to items on the PAI.

Despite a convincing argument for the superiority of actuarial classifications and predictions when compared to unstructured clinical judgment in health care and other settings, mental health professionals have been slow to adopt actuarial classification methods, presumably for a number of reasons. In some cases, actuarial tools do not exist. For example, valid actuarial tools have not been developed to classify a defendant as competent or incompetent to stand trial, or to identify whether the best interests of a child are better met by living with a specific parent. Second, mental health professionals sometimes do not use existing tools because they have concerns about differences on important characteristics between the individuals with whom they are working and the individuals in the groups on which the tools were developed (e.g., Is it appropriate for an Australian psychologist to use the VRAG—a tool developed and validated in North America—to make a judgment about the likelihood that an Aboriginal offender will reoffend if returned to the Outback?). Finally, some commentators (e.g., Hilton et al. 2006) have offered that mental health professionals are reluctant to adopt these tools because they threaten their professional identity and prestige.

RESPONSIBLE USE OF PSYCHOLOGICAL ASSESSMENT TOOLS IN FORENSIC PSYCHIATRIC EVALUATIONS

How and in what way psychiatrists might use psychological assessment tools when conducting forensic evaluations are affected by a number of factors. These are addressed below.

Need and value

The first matter to consider is need and value. Are there some forensic evaluation contexts in which psychological testing may prove of assistance in addressing issues before the legal decision maker? The obvious answer is yes. Use of psychological assessment instruments can improve the utility of forensic psychiatric and forensic psychological evaluations assuming the instruments relied upon are valid assessments of behaviors or capacities that are in some way relevant to issues before the legal decision maker, or if they work in a way that ensures that the evaluation is more relevant, reliable, and valid.

For example, making a decision about whether a person who has been convicted of first-degree murder is ineligible for the death penalty as a result of intellectual disability will be informed by psychological testing. Judgments about the genuineness of psychotic spectrum symptoms reported by a Social Security Disability Income applicant will be more accurate if they are based on the results of psychological tests that are designed to identify people feigning such impairment (rather than the general impressions of an examiner). And an examiner's evaluation of and judgment about a defendant's ability to understand and participate in the criminal justice process will be more reliable and valid if he or she employs a tool that ensures a comprehensive inquiry into all psychiatric/psychological factors and legal factors that can affect trial competence. Use of psychological assessment tools is not always necessary, however, or without its problems.

Podboy and Kastl (1993) asserted that confirmatory bias (a tendency to seek and focus on data that confirm or are consistent with initial hypotheses and ignore or disregard disconfirming data) may operate with forensic examiners who use tests insofar as they reference test data that are consistent with their clinical impressions and ignore those data that run contrary. They also expressed concern that examiners who use tests could overly emphasize test results and fail to consider their limitations. Along similar lines, Wakefield and Underwager (1993) warned against overinterpretation of test results in forensic examination contexts.

Overreliance on the same test battery in all forensics evaluation can be problematic as well. Selection of tests and tools requires judgment and thoughtfulness. Greenberg et al. (2003), for example, described how using the same battery of tests and measures in all personal injury evaluations could be problematic. Tests of cognitive functioning, for instance, would not automatically be advised when the person being evaluated is not asserting cognitive impairment. Similarly, a forensic examiner should be less inclined to use an intelligence test in a competency to stand trial evaluation of a defendant who has a college degree, stable employment history, appropriate verbal skills, and no history of head injuries. Here, testing intelligence offers low incremental value, as this particular defendant would likely have at least minimal intellectual capacity to stand trial. If, however, this defendant has recently begun to exhibit disorganized speech and reported delusions and hallucinations with no prior history of mental health treatment, tests of personality and response style could offer additional diagnostic clarity.

Competence

Use of an assessment tool can only prove helpful if the user is competent in its administration and interpretation. The American Medical Association Code of Medical Ethics and licensing laws of all states obligate physicians to practice competently. Similarly, the Ethics Guidelines for the Practice of Forensic Psychiatry (American Academy of Psychiatry and the Law 2005) require that forensic psychiatrists claim expertise "only in areas of actual knowledge, skills, training, and experience" (p. 4).

The most authoritative reference for requirements of tests and test users are the *Standards for Educational and Psychological Testing* (Joint Committee 2014), which were developed by an interdisciplinary committee representing the American Educational Research Association, the American Psychological Association, and the National Council on Measurement in Education (Joint Committee 2014). Now in their third iteration, the purpose of the standards is to provide criteria for sound test development and use, and they are intended for use by "professionals who specify, develop, or select tests and for those who interpret, or evaluate the technical quality of, test results" (Joint Committee 2014, 1).

As a joint statement of three major professional organizations, the standards wield considerable authority. Regulatory authorities and courts have recognized them as establishing generally accepted standards for test use and development. Furthermore, "[c]ompliance or noncompliance with the Standards may be used as relevant evidence of legal liability in judicial and regulatory proceedings" (Joint Committee 2014, 2).

Considerable attention is paid in the standards to the issue of test user competence. Standard 9.0 directs that, "Test users are responsible for knowing the validity evidence in support of the intended interpretations of scores on tests that they use, from test selection through the use of scores, as well as common positive and negative consequences of test use" (Joint Committee 2014, 142). Standard 9.2 directs that, "Prior to adoption and use of a published test, the test user should study and evaluate test materials provided by the test developer. Of particular importance are materials that summarize the test's purpose, specify the procedure for test administration, define the intended population(s) of test takers, and discuss score interpretations for which validity and reliability/precision data are available" (Joint Committee 2014, 142).

Additional discussion of competence is included in Section 10 of the standards, which is devoted to psychological testing and assessment. Standard 10.2 directs that professionals who use psychological tests "should be familiar with the relevant evidence of validity and reliability/precision for the intended uses of the test scores and assessments, and should be prepared to articulate a logical analysis that supports all facets of the assessment and the inferences made from the assessment" (Joint Committee 2014, 164).

Competence to administer psychological assessment measures presumably varies considerably among psychiatrists. There are certainly some psychiatrists who have a sophisticated understanding of psychometric theory and a number of the assessment tools that are often employed in forensic evaluation contexts, just as there are some psychologists who have a sophisticated understanding of the actions

and mechanisms of many psychoactive medications. It is likely, however, that few psychiatrists have completed formal training in psychological assessment and measurement that is required to administer, score, and interpret many psychological assessment tools.

Using assessment tools for which one does not have the requisite knowledge and skills certainly constitutes incompetent practice—for both psychiatrists and psychologists. The risks associated with incompetent test use are significant. Perhaps most importantly, inaccurate opinions may be formed and offered about the examinee's functioning. In addition, opinions that are anchored—in full or in part—in testing that has been incompetently administered, scored, or interpreted may be barred or, at the very least, challenged. And finally, psychiatrists and psychologists may be subject to malpractice or licensing actions (see, e.g., *Texas State Board of Examiners of Psychologists v. Denkowski* 2011).

THE ALLURE OF COMPUTERIZED PSYCHOLOGICAL TEST ADMINISTRATION, SCORING, AND INTERPRETATION

Largely facilitated by development and regular use of the personal computer, computerized psychological test administration, scoring, and interpretation has become increasingly common. Whereas some tests still must be administered by an examiner but can be scored and interpreted via computer (e.g., measures of intelligence such as the WAIS-IV), others can be computer administered, scored, and interpreted (e.g., measures of emotional and behavioral functioning such as the MMPI-2-RF, PAI, and Trauma Symptom Inventory-Revised [TSI-R]).

The value of computer-based test administration and scoring primarily lies in the reduction of scoring errors associated with "hand scoring." This application is significant because scoring errors are not uncommon (Allard et al. 1995; Allard and Faust 2000; Simons et al. 2002). Although computerized interpretive programs have considerable potential value, they also can prove dangerous insofar as they tempt mental health professionals to use tests about which they are not sufficiently knowledgeable. Although this challenge applies to all mental health professionals, psychologists are presumably at less risk given their formal training in psychometric theory and test administration, scoring, and interpretation.

The intricacies of computerized test interpretation are reflected in the ethics code of the American Psychological Association (American Psychological Association 2010). Section 9.06 of the Ethical Principles of Psychologists and Code of conduct directs that, "When interpreting assessment results, including automated interpretations, psychologists take into account the purpose of the assessment as well as the various test factors, test-taking abilities and other characteristics of the person being assessed, such as situational, personal, linguistic and cultural differences, that might affect psychologists' judgments or reduce the accuracy of their interpretations" (American Psychological Association 2010, 13). More directly addressing the challenge of computerized test interpretation, Section 9.09 of the ethics code directs, "[p]sychologists select scoring and interpretation services (including automated services) on the basis of evidence of the validity of the program and procedures as well as on other appropriate considerations… Psychologists retain responsibility for the appropriate application, interpretation and use of assessment instruments, whether they score and interpret such tests themselves or use automated or other services" (American Psychological Association 2010, 13).

The Standards for Educational and Psychological Testing (Joint Committee 2014) include language indicating that use of computerized psychological test administration, scoring, and interpretive programs by professionals not trained in psychometric theory and psychological assessment is problematic. In addition to the general knowledge and competence requirements discussed above, Standard 9.10 directs, "Test users should not rely solely on computer-generated interpretations of test results" (Joint Committee 2014, 145). Associated commentary in the Standards describes the potential for automated narrative reports to be misleading and references the need for professional judgment. Standard 10.17 directs that professionals who use computer-generated interpretations of psychological test data "should verify that the quality of the evidence of validity is sufficient for the interpretation" (Joint Committee 2014, 168). Associated commentary notes that computer-generated interpretations may result in misleading or oversimplified analyses of the meanings of psychological test scores.

Put bluntly, mental health professionals who use computers to administer, score, and/or interpret psychological tests must (1) have an adequate foundation in psychometric theory, (2) be knowledgeable about the development and appropriate use of the test, and (3) understand the basis for administration, scoring, and/or interpretive process. Without such competence, the professional cannot adequately judge the validity of the product and results, and the professional cannot speak to their meaning.

In response to the above, a reasonable question is whether, for psychiatrists who do not meet the requirements above, there is a meaningful difference between (1) using a computer to administer, score, and interpret a psychological test, and (2) referring the examinee to a psychologist who administers, scores, and interprets the same psychological test. There is a significant difference in these practices insofar as, in the latter case, the referral makes clear the psychiatrist's (1) lack of expertise in test administration, scoring, and interpretation, and (2) reliance on a consultant to provide opinions upon which the psychiatrist may rely when forming his or her own expert opinions. In the former case the psychiatrist can and should be held to answer questions about the psychometric properties of the test and any associated matters regarding its administration, scoring, and interpretation. In the latter

case the psychiatrist could not be held to answer questions about these matters, any more than he or she could be held to answer questions about the properties of a PET scan machine that was used to produce a brain image upon which a consulted neurologist relied.

As an example, we equate a psychiatrist selecting and, via computer, administering, scoring, and interpreting tests like the MMPI-2-RF or PAI to a psychiatrist not qualified in neurology selecting the type of neurologic scan and contrast that will be run, and then reading and interpreting a computerized interpretation of the results. We think few, if any forensic psychiatrists would consider doing the latter. Rather, they would contact a neurologist, share with the consultant their challenge, and rely on the neurologist's expertise with respect to test selection, administration, and interpretation.

Psychiatrists should tread cautiously when considering use of assessment tools, keeping in mind the above considerations. That being said, there is considerable variability with respect to the knowledge and skills required to employ various assessment tools. As a result, from our perspective, there are two primary ways in which psychiatrists may employ psychological assessment tools in forensic evaluation. We discuss each below.

PSYCHIATRISTS' USE OF PSYCHOLOGICAL ASSESSMENT TOOLS

There are a considerable number of psychological assessment tools that are appropriate for psychiatrists to use when conducting forensic evaluations. Psychiatrists appear well situated to employ most, if not all, SPJTs when conducting forensic evaluations. Given that a purpose of SPJTs is to increase the reliability and validity of clinical judgments, psychiatrists (and psychologists) would do well to routinely use SPJTs for those forensic assessment tasks for which they exist. Recent research indicates that even evaluations that appear relatively straightforward such as competence evaluations, may be less reliable (and valid) than initially claimed (Murrie et al. 2008). Structured professional judgment tools that direct the examiner to consider legally relevant or empirically valid factors have the potential to improve the reliability and validity of judgments about diverse matters of concern to forensic psychiatrists and forensic psychologists such as competence to proceed with the legal process, competence to be executed, risk for general reoffending, risk for violence, and risk for domestic violence.

Perhaps most importantly, given the format and structure of SPJTs, advanced training in or understanding of psychometric theory and assessment are not required. Rather, all that is required for their use is an understanding of the construct that any particular tool is designed to assess or assist in assessing (e.g., violence risk, competence to stand trial), as well as the strategy employed by the developers when selecting tool items. Critical to using SPJTs is understanding and communicating to the legal decision maker that they are not tests, but rather tools that structure professional, clinical judgments to ensure a comprehensive consideration of factors that are relevant to understanding a particular psycholegal issue that is in dispute.

Indeed, that SPJTs are appropriate for use by psychiatrists is suggested in the manuals of many SPJTs, a sampling of which is offered in Table 68.4.

Table 68.4 Sample language describing qualifications for use of various structured professional judgment tools

Fitness Interview Test-Revised (FIT-R)	"Evaluations of competence to stand trial should be conducted by mental health professionals, typically psychologists and psychiatrists but also social workers and nurse practitioners in some jurisdictions…The FIT-R is, we believe, well-suited to assist any professional qualified to conduct [competence to stand trial] evaluations" (Roesch et al. 2006, 23–24).
Spousal Assault Risk Assessment (SARA) Guide	"The SARA is not a test or scale in the usual sense of these terms…Because the SARA is not a controlled psychological test and is intended for use in many different contexts, there is no single set of qualifications for users. When the SARA is used to evaluate and make decisions about an individual, users are responsible for ensuring that their evaluation conforms to relevant laws, regulations and policies. In addition, users should meet the following minimum qualifications: (1) Expertise in individual assessment…(2) Expertise in the area of spousal assault" (Kropp et al. 1995 3, 12–13).
Structured Assessment of Violence Risk in Youth (SAVRY)	"The SAVRY is designed for use by professionals in a variety of disciplines who conduct assessments and/or make intervention/supervision plans concerning violence risk in youth…At a minimum, those who use the SAVRY should have expertise (i.e., training and experience) in conducting individual assessments, child/adolescent development, and in youth violence. In general, psychologists, psychiatrists, trained juvenile probation officers and social workers with requisite expertise would be qualified to use the SAVRY" (Borum et al. 2000, 15).

Table 68.5 Sample language describing qualifications for use of various psychological tests

Inventory of Legal Knowledge (ILK)	"In accordance with the Standards for Educational and Psychological Testing…ILK results should only be interpreted by professionals with sufficient coursework and training from an accredited college or university in psychological assessment and in the use and interpretation of psychological tests" (Otto et al. 2010, 7).
MacArthur Competence Assessment Tool-Criminal Adjudication (MacCAT-CA)	"Consistent with guideline offered in the Standards for *Educational and Psychological Testing*…clinical interpretation of the MacCAT-CA also requires professional training in psychological assessment and psychopathology" (Poythress et al. 1999, 5).
Minnesota Multiphasic Personality Inventory-2-RF (MMPI-2-RF)	"The Standards for Educational and Psychological Testing require that 'prior to the adoption and use of a published test, the test user should study and evaluate the materials provided by the test developer…At a minimum, these include the manual provided by the test developer. Ideally the user should be conversant with relevant studies reported in the professional literature' (AERA et al., p. 113). This includes reviewing and evaluating psychometric data on the reliability and validity of scale scores. To conduct a competent review of the MMPI-2-RF documentation and literature and this conform to this standard, the user must have graduate-level training in psychological testing and assessment and be familiar with the means by which basic psychometric functioning of test scores—such as reliability, measurement error, the various facets of validity, classification statistics and accuracy analyses, norms, and the derivation of standard scores—are evaluated. In summary, competent use of the MMPI-2-RF requires graduate-level training in psychological testing and assessment with a specific emphasis on basic psychometric, graduate-level training in the areas of personality and psychopathology, graduate and/or continuing education training on the MMPI instruments, supervised experienced in the administration, soring, and interpretation of the test, and familiarity with the current professional literature on the instrument" (Ben-Porath and Tellegen 2013, 10).
Personality Assessment Inventory (PAI)	"Interpretation of PAI profiles and test score patterns is solely the province of qualified professionals and requires training in the basics of psychometric assessment as well as descriptive psychopathology" (Morey 2007, 7).

PSYCHIATRISTS' RELIANCE ON PSYCHOLOGICAL CONSULTATION

As suggested previously, a comprehensive understanding of measurement theory addressing matters such as test construction, test reliability (inter-rater, split half, test–retest, alternative forms), test validity (e.g., face, discriminant, convergent), and test classification (e.g., sensitivity, specificity, positive predictive power, negative predictive power) is necessary to administer, interpret, and score many psychological measures. Thus, few psychiatrists will have the requisite knowledge and skills. Indeed, the complicated nature of many of these assessment techniques and the need for this knowledge are reflected in the administration manuals of many psychological tests.

There are many psychological tests that psychiatrists should not administer or interpret given their complexity. Rather, they would do well to refer forensic examinees for whom such testing is necessary to a psychologist competent to administer the construct at issue—much like they do with their medical specialist colleagues. Ideally, the psychiatrist would describe the matter in question and, with the psychologist, come to an agreement about the best tools to use.

Provided in Table 68.5 are excerpts from the manuals of a number of tests, all of which make reference to specialized knowledge about and training in psychometric theory and psychological assessment that is probably not possessed by many psychiatrists. An aggressive cross-examination regarding the development of the tool, its limitations, and the competencies required of someone administering, scoring, and interpreting these tests may prove damaging.

SUMMARY

Forensic psychiatrists and forensic psychologists can provide legal decision makers with helpful information if their evaluations of litigants are structured or informed by valid assessment techniques. Forensic assessment can be enhanced by implementing assessment tools when appropriate.

SUMMARY KEY POINTS

- A model for forensic assessment (Grisso 1986, 2003) applies the following steps: be familiar with the relevant law, understand what legal matters may be impacted by the examinee's emotional, behavioral, and/or cognitive functioning, and select the assessment technique(s) that best aid in assessment of identified psycholegal capacities.
- Assessment tools can be classified as the following: clinical assessment techniques (CATs), forensically relevant assessment techniques (FRATs), and forensic assessment techniques (FATs).
- Assessment tools can also be classified according to how they function: norm-based assessment tools (tests), structured professional judgment tools, and actuarial assessment tools.
- Responsible use of psychological assessment tools in forensic psychiatric evaluations requires forensic psychiatrists and psychologists to consider the following: need and value of assessment tools; competence in administering, scoring, and interpreting assessment tools; and special considerations when using computerized test administration, scoring, and interpretation.
- Psychiatrists may benefit by using psychological assessment tools, such as SPJTs, that increase the reliability and validity of clinical judgments.
- Psychiatrists may rely on psychological consultation such as when a comprehensive understanding of matters such as test construction, test reliability, test validity, and test classification is needed.

Violence risk assessment: The state of the science

JENNIFER L. SKEEM AND JOHN MONAHAN

INTRODUCTION

Forensic psychiatry and psychology have grown tremendously over recent years as assessment-focused specialties. A variety of forensic assessment instruments have been developed to help mental health clinicians evaluate legally relevant questions about individuals involved in the civil-, criminal-, or juvenile-justice systems. Many of these instruments improve clinicians' ability to forecast the likelihood that an individual will behave violently. Increasingly, these instruments are being applied in response to statutes and regulations that require specialized assessments to identify "high-risk" individuals for initiating some form of preventive intervention, or "low-risk" individuals for eschewing (or terminating) such intervention.

In this chapter, we provide a current snapshot of the field of violence risk assessment. After highlighting the contexts in which risk of violence is assessed, we describe a framework for understanding alternative approaches to risk assessment and then compare the utility of these approaches in predicting violence. Before considering possible future developments in the field, we draw attention to two recent debates, i.e., whether group-based instruments are useful for assessing an individual's risk, and whether the pursuits of risk assessment and risk reduction should be separated.

We wish to be clear at the outset about our terminology and scope. We endorse the general definition of risk assessment given by Kraemer et al. (1997, 340): "The process of using risk factors to estimate the likelihood (i.e., probability) of an outcome occurring in a population." These authors define a risk factor as a correlate that precedes the outcome in time, with no implication that the risk factor and the outcome are causally related (e.g., past violence is a robust risk factor for future violence). Our outcome of focus is physical violence to others.

LEGAL DEVELOPMENTS

The populations in which violence risk is assessed vary across many disparate legal contexts. In the mental health system, civil commitment on the ground of "dangerousness," commitment as a sexually violent predator, and the tort liability of psychiatrists and psychologists for their patients' violence often turn on issues of risk assessment. In the justice system, risk assessment is increasingly being used to inform decisions about sentencing and parole. Risk assessment for violent terrorism is also becoming increasingly common.

The law regulating the process of violence risk assessment has become much more developed in the United States in recent years. Some laws specify risk factors that may and may not be used to estimate risk (e.g., race is constitutionally proscribed as a risk factor, whereas gender and age are generally permitted; see Monahan, 2013). Other laws allude to specific likelihoods of violence necessary to trigger preventive actions. For example, a Virginia statute allows for the civil commitment of a person with mental illness if there is a "substantial likelihood" that the person will cause serious physical harm to himself or herself or others in the near future, as a result of mental illness. The material used to train professionals in the law elaborates on the meaning of substantial likelihood: "a 'one-in-four' estimated risk of serious harm in the near future is sufficient, particularly when the harm being threatened is potentially fatal… A 'substantial risk' is *not* meant to mean 'more likely than not' (51%)" (Cohen et al. 2009, 133).

ASSESSMENT ALTERNATIVES

No distinction in the history of risk assessment has been more influential than Meehl's (1954) cleaving the field into "clinical" and "actuarial" (or statistical) approaches.

Subsequent research is fairly characterized in a comprehensive review by Ægisdóttir et al. (2006, 368): "one area in which the statistical method is most clearly superior to the clinical approach is the prediction of violence." In recent years, however, a plethora of instruments has been published that are not adequately characterized by a simple clinical–actuarial dichotomy. Rather, the risk assessment process now exists on a *continuum of rule-based structure*, with completely unstructured ("clinical") assessment occupying one pole of the continuum, completely structured ("actuarial") assessment occupying the other pole, and several forms of partially structured assessment lying between the two (Skeem and Monahan 2011).

The violence risk assessment process, in this regard, might usefully be seen as having four components: (1) identifying empirically valid (and legally acceptable) risk factors, (2) determining a method for measuring ("scoring") these risk factors. (3) establishing a procedure for combining scores on the risk factors, and (4) producing an estimate of violence risk. It is possible to array five current approaches to violence risk assessment according to whether the approach structures (i.e., specifies rules for generating) none, one, two, three, or all four of these components of this process. Purely "clinical" risk assessment structures *none* of the four components. The clinician selects, measures, and combines risk factors, and produces an estimate of violence risk, as his or her clinical experience and judgment indicate.

Performing a violence risk assessment by reference to a standard list of risk factors that have been found to be empirically valid (e.g., age, past violence, substance abuse), such as the lists provided in psychiatric texts structures *one* component of the process. Such lists function as an *aide memoir* to identify the risk factors the clinician should attend to in conducting his or her assessment, but they do not further specify a method for measuring these risk factors. As Tardiff (2008, 5) has stated, "Some factors may be more important than others for the individual patient."

The "structured professional judgment" approach exemplified by the HCR [Historical Clinical Risk Management]-20 (Webster et al. 1997) structures *two* components of the violence risk assessment process: the identification and measurement of risk factors, which may be scored as 0 if absent, 1 if possibly present, or 2 if definitely present. A revised version of this instrument—HCR-20 (Version 3)—has recently been released (Douglas et al. 2013). Structured professional judgment instruments do not go further and structure how the individual risk factors are to be combined in clinical practice (Douglas et al. 2014). Approaches to risk assessment that structure *three* components of the risk assessment process are illustrated by the Classification of Violence Risk (COVR) (Monahan et al., 2001). This instrument structures the identification, measurement, and combination of risk factors (via a classification tree design). But those who developed this instrument do not recommend that the final risk assessment reflect *only* the combined scores on the assessed risk factors. Given the possibility that rare factors influence the likelihood of violence in a particular case—and that, precisely because such factors rarely occur, they will never appear on an actuarial instrument—a professional review of the risk estimate is advised (while realizing that clinicians may overidentify "rare" factors). This professional review "would not revise or 'adjust' the actuarial score produced by the COVR, but would likely be of a more qualitative nature (e.g., 'higher than' or 'lower than' the COVR estimate)" (Monahan 2010, 195). A validation of the COVR in Sweden has recently been published (Sturup et al. 2013).

The best-known forensic instrument that structures all *four* of the components of the violence risk assessment process—i.e., that is *completely* actuarial—is the Violence Risk Appraisal Guide (VRAG). This instrument not only structures the identification, measurement, and combination of risk factors, it also specifies that once an individual's violence risk has been actuarially characterized, the risk assessment process is complete. As Quinsey et al. (1998, 197) have stated, "What we are advising is not the *addition* of actuarial methods to existing practice, but rather the *replacement* of existing practice with actuarial methods." A revision of the VRAG has recently been published (Rice et al. 2013).

DOES ONE ASSESSMENT APPROACH PREDICT BETTER THAN ANOTHER?

Of these five approaches, the unstructured ("clinical") one rests upon the least empirical support. In one major study of this approach, Lidz, Mulvey, and Gardner (1993, 1010) concluded that "clinical judgment has been undervalued in previous research. Not only did the clinicians pick out a statistically more violent group, but the violence that the predicted group committed was more serious than the acts of the comparison group. Nonetheless, the low sensitivity and specificity of these judgments show that clinicians are relatively inaccurate predictors of violence."

We know of no research that systematically compares the predictive utility of strategies that structure none, one, two, three, or all four components of the process. Relevant data are available, however, on approaches that structure two or more components. Recent debates about whether it is more appropriate to structure clinical judgment (e.g., HCR-20) or replace it altogether (e.g., VRAG) has prompted a number of horse races that compare the predictive efficiency of one risk assessment instrument against another.

Taken together, these studies provide little evidence that one validated instrument predicts violence significantly better than another. In a recent meta-analysis of 28 studies that controlled well for methodological variation across studies, Yang et al. (2010) found that the predictive efficiencies of nine risk assessment instruments (including the HCR-20 and VRAG) were essentially "interchangeable," with point estimates of accuracy falling within a narrow band (i.e., AUC = 0.65–0.71). Although most of these studies used total scores on the HCR-20 rather than structured clinical judgments (low/medium/high risk), there is some evidence that those judgments both predict

violence and add incremental predictive utility to scores derived by actuarially combining items (see Heilbrun et al. 2009). But this latter claim is contested (Hanson and Morton-Bourgon 2009).

The results of the meta-analysis by Yang et al. (2010) are consistent not only with other syntheses of risk assessment research (e.g., Campbell et al. 2009; Olver et al. 2009), but also with the dominant message that has emerged from meta-analyses of alternative psychotherapy techniques. As pronounced by the Dodo bird at the end of the race in Lewis Carroll's *Alice's Adventures in Wonderland* (2011, 80), "*Everybody* has won, and *all* must have prizes."

Why might different instruments perform equally well in predicting violence? One persuasive explanation is that they tap "common factors" or shared dimensions of risk, despite their varied items and formats. In an innovative demonstration, Kroner, Mills, and Reddon (2005) printed the items of several leading instruments on strips of paper, placed the strips in a coffee can, shook the can, and then randomly selected items to create four new tools. The authors found that the "coffee can instruments" predicted violent and nonviolent offenses as well as the original instruments. In a recent extension of this approach to sex offenders, Buttars and Huss (2014) found that "coffee can instruments" predicted *better* than original instruments. Based on a factor analysis of the tools' items, Kroner et al. (2005) found that the instruments tap four overlapping dimensions: criminal history, an irresponsible lifestyle (e.g., poor engagement in school/work), psychopathy and criminal attitudes (e.g., entitlement), and substance abuse-related problems. Despite surface variation, then, instruments may generally tap "a longstanding pattern of dysfunctional and aggressive interpersonal interactions and antisocial and unstable lifestyle that are common to many perpetrators of violence" (Yang et al. 2010, 743).

The strongest risk factors for violence seem to be shared not only among risk assessment instruments, but also across key groups (e.g., Bonta et al. 2013). In particular, an increasing body of research suggests that only a small proportion of violence committed by people with mental illness—perhaps as little as 10%—is directly caused by symptoms (Skeem et al. 2011). Most people with mental illness share leading risk factors for violence with their relatively healthy counterparts.

ARE EMPIRICALLY BASED INSTRUMENTS USEFUL FOR INDIVIDUALS?

One issue that has generated much recent controversy is Hart, Cooke, and Michie's (2007, S60) argument that the margins of error surrounding individual risk assessments of violence are so wide as to make such predictions "virtually meaningless." As stated by Cooke and Michie (2010, 259), "on the basis of empirical findings, statistical theory, and logic, it is clear that predictions of future offending cannot be achieved, with any degree of confidence, in the individual case" (see also Hart and Cooke 2013).

This position has been vigorously contested, both with respect to the overall argument and application of statistics to make it. For example, Hanson and Howard (2010) demonstrate that the wide margin of error for individual risk assessments is a function of having only two possible outcomes (violent or not violent) and therefore conveys nothing about the predictive utility of a risk assessment tool, which must be judged by other criteria. Because all violence risk assessment approaches, not just actuarial approaches, yield some estimate of the likelihood that a dichotomous outcome will occur, none are immune from Hart et al.'s argument (as they recognize). Indeed, their argument "if true, . . . would be a serious challenge to the applicability of any empirically based risk procedure to any individual for anything" (Hanson and Howard 2010, 277).

Our view is that group data theoretically can be, and in many areas empirically are, highly informative when making decisions about individual cases (Scurich et al. 2012). Consider two examples from other forms of risk assessment. In the insurance industry, "until an individual insured is treated as a member of a group, it is impossible to know his expected loss, because for practical purposes that concept is a statistical one based on group probabilities. Without relying on such probabilities, it would be impossible to set a price for insurance coverage at all" (Abraham 1986, 79). In weather forecasting, "extensive statistical data are available on the average probability of the events [meteorologists] are estimating" and therefore when meteorologists "predict a 70 percent chance of rain, there is measurable precipitation just about 70 percent of the time" (National Research Council 1989, 46). In addition, consider the revolver analogy of Grove and Meehl:

> Suppose you are a political opponent held in custody by a mad dictator. Two revolvers are put on the table and you are informed that one of them has five live rounds with one empty chamber, the other has five empty chambers and one live cartridge, and you are required to play Russian roulette. If you live, you will go free. Which revolver would you choose? Unless you have a death wish, you would choose the one with the five empty chambers. Why? Because you would know that the odds are five to one that you will survive if you pick that revolver, whereas the odds are five to one you will be dead if you choose the other one. Would you seriously think, "Well it doesn't make any difference what the odds are. Inasmuch as I'm only going to do this once, there is no aggregate involved, so I might as well pick either one of these two revolvers; it doesn't matter which"? (Grove and Meehl 1996, 305–306)

The probabilities associated with risk assessment clearly are less certain than those associated with the number of

bullets in a six-chamber revolver. Nevertheless, we find compelling Grove and Meehl's basic point that group data can powerfully inform individual assessments of risk.

We agree with Mossman (2015) that "something in the Hart-Cooke-Michie argument must be wrong." Mossman uses a medical rather than a ballistic analogy to make the same point as Grove and Meehl: "A 50-year-old individual who learns that half of people with his diagnosis die in five years will find this information very useful in deciding whether to purchase an annuity that would begin payouts only after he reached his 65th birthday."

Similarly, if all one knew about an individual was his or her Static-99R score and that he or she came from a population to which the Static-99R data and rates were relevant, the individual's Static-99R score would be the best and the only basis for making a probabilistic judgment about his or her behavior. This is true despite our belief that many factors not considered by the Static-99R (e.g., the person's employment status, substance use, or family relationships) affect sex offenders' likelihood of recidivism.

Finally, Faigman et al. (2014) have recently analyzed how the law deals with what they refer to as group-to-individual ("G2i") inference in scientific expert testimony, including scientific expert testimony on violence risk. They conclude:

> It is customary in the ordinary practice of medicine and related fields (e.g., clinical psychology) for professionals to make individual… judgments derived from group-based data. Likewise, it is *not* customary in the ordinary practice of sociology, epidemiology, anthropology, and related fields (e.g., cognitive and social psychology) for professionals to make individual… judgments derived from group-based data. (Faigman et al. 2014)

In the view of these authors, evidence-based scientific expert testimony on an individual's violence risk when offered by qualified psychiatrists or clinical psychologists should have no trouble being admitted in court.

SHOULD RISK ASSESSMENT AND REDUCTION BE SEPARATED?

Risk assessment has become big business in the U.S. justice system, principally because "the fiscal condition of most American jurisdictions is so dire that maintaining what is by international standards an absurdly bloated prison population is simply not a sustainable option" (Monahan and Skeem 2014, 158). Risk assessment can facilitate prison downsizing directly, by identifying for release those inmates who are least likely to return.

Risk assessment can also be used in the service of risk reduction. Correctional agencies that manage a staggering number of youth and adults are increasingly endorsing structured risk assessment approaches and treatment programs that reduce reoffending by targeting risk factors like anger, poor self-control, and antisocial attitudes. In this context, companies have begun marketing complex (and poorly validated) assessment systems that explicitly include treatment-relevant variables in their risk estimates and ostensibly serve the risk reduction enterprise better than simple actuarial tools. Fundamental requirements for developing, (cross-)validating, and applying risk assessment tools are "routinely ignored or violated" (Gottfredson and Moriarty 2006; see also Skeem and Eno Louden 2007).

This has sparked debate about whether the pursuit of risk assessment and risk reduction should be separated or integrated. Baird (2009) favors separation, arguing that the addition of treatment-relevant variables to otherwise parsimonious risk equations that emphasize past (mis)behavior will dilute their predictive utility. Andrews (2012), on the other hand, argues that some treatment-relevant variables are risk factors and should be integrated in risk estimates. His view is that efficient prediction can be achieved by statistically selecting and combining a few highly predictive risk factors, but tools that sample risk domains more broadly and include treatment-relevant risk factors can be equally predictive. Andrews' (2012) view is consistent with evidence that tools that differ in their inclusion of such factors yield similar predictive efficiencies (Campbell et al. 2009; Olver et al. 2009; Yang et al. 2010).

Monahan and Skeem (2014, 160) observed that this debate has been exacerbated by confusion about what a treatment-relevant risk factor is, exactly. They differentiated among the four different types of risk factors for violent reoffending or recidivism shown in Table 69.1. A *fixed marker* is a risk factor that cannot be changed (e.g., early onset of antisocial behavior). In contrast, both *variable markers* and *variable risk factors* can be shown to change over time. Variable markers (like age) cannot be changed through intervention, unlike variable risk factors (like employment problems). *Causal risk factors* are variable risk factors that,

Table 69.1 Four types of risk factors

Type of risk factor	Definition	Example
Fixed marker	Unchangeable	Gender
Variable marker	Unchangeable by intervention	Age
Variable risk factor	Changeable by intervention	Employment status
Causal risk factor	Changeable by intervention; when changed, reduces recidivism	Substance abuse

Source: Adapted from Kraemer HC et al. 1997. *Archives of General Psychiatry* 54:337–343; Monahan J and J Skeem. 2014. *Federal Sentencing Reporter* 26:158–166.

when changed through intervention, can be shown to change the risk of recidivism.

All four types of risk factors are relevant to *risk assessment,* but only causal risk factors are relevant to *risk reduction.* Put simply, treatment-relevant risk factors are causal risk factors. Unless a variable risk factor has been shown to be causal, there is little reason to assume that reducing the risk factor will reduce violence.

This fact is rarely recognized in current discourse. Instead, variable risk factors have been confused with causal risk factors under the rubric of "dynamic risk factors" or "criminogenic needs." Although the latter phrases typically reference a variable risk factor that *theoretically* can be changed through intervention to reduce risk, these phrases tend to be misused as synonyms for causal risk factors.

The most compelling form of evidence that a risk factor was causal would be a randomized controlled trial in which a targeted intervention was shown to be effective in changing one or more variable risk factors, and the resulting changes were shown to reduce the likelihood of post-treatment recidivism. As Monahan and Skeem (2014) observe, it is nearly impossible to locate such randomized controlled tests.

Although little is known about causal risk factors, there is increasing evidence that some risk factors are variable—that they change over time, and that change predicts re-offending (e.g., Howard and Dixon 2013). Variable risk factors have been shown to predict proximate violence and are the best point of reference the field presently has to offer for risk reduction. For example, in a randomized controlled trial, Bonta et al. (2012) found that, compared to untrained probation officers, specially trained probation officers spent more time discussing variable risk factors with their probationers (e.g., procriminal attitudes, antisocial associates), and their probationers manifested greater reductions in recidivism risk. Although little is known about which variable risk factors are causal, variable risk factors can be repeatedly assessed to monitor ebbs and flows in an offender's risk, and adjust levels of supervision and services accordingly.

PURPOSE-BASED CHOICE AMONG VALID INSTRUMENTS

Given a pool of instruments that are well-validated for the groups to which an individual belongs, our view is that the choice among them should be driven by the ultimate purpose of the evaluation. If the ultimate purpose is to characterize an individual's likelihood of future violence relative to other people, then choose the most efficient instrument available. This is appropriate for a single event decision in which there is no real opportunity to modify the risk estimate based on future behavior (Heilbrun 1997). If the ultimate purpose is to manage or reduce an individual's risk, then value may be added by choosing an instrument that includes treatment-relevant risk factors. (Although an integrated instrument would do, Mills and Gray [2013] demonstrate the utility of a two-stage process in which a risk assessment step is followed by a risk management step.) This choice is appropriate for ongoing decisions where the risk estimate can be modified to reflect ebbs and flows in an individual's risk over time. Beyond focusing risk-reduction efforts, these instruments could provide incentive for changing behavior (a parole board cannot advise an inmate to "undo" his past commission of an assault but can advise him to develop employment skills).

This view comes with three important caveats. First, techniques that include treatment-relevant risk factors will add no value to simpler approaches unless the risk assessment is followed by a period of control over the individual during which those factors are translated into an individual supervision and treatment plan (rather than simply filed away) and systematically targeted with appropriate services (rather than ignored in resource allocation). Risk reduction cannot be achieved through risk assessment alone, regardless of the approach applied. Second, treatment-relevant variables can and do appear in statistically derived risk assessment instruments (Monahan 2010); an instrument's degree of structure cannot be equated with its relevance to risk reduction. Third, even well-validated instruments offer little direct validity data for the treatment-relevant variables they include. It is not enough to demonstrate that a variable is a risk factor for violence; here, it must further be shown that the variable reduces violence risk when deliberately changed by treatment (i.e., is a *causal* risk factor; Kraemer et al. 1997). Causality is not a given: In one of the few studies to address this topic, Kroner and Yessine (2013) found that change in a treatment-targeted risk factor did *not* explain reduced risk of reoffending. This is a crucial issue to address in future research, if tools continue to be sold on the promise of informing risk reduction.

FUTURE DIRECTIONS

The violence risk assessment field may be reaching a point of diminishing returns in instrument development. It has long been argued that there may be a "sound barrier" to predictive validity in this area, such that the effect size of risk estimates for predicting criterion measures rarely exceeds a correlation of 0.40 (Menzies et al. 1985) or an AUC of .72 (Rice and Harris 2005). In this regard, Appelbaum (2011) has stated that "predictive assessments are the most challenging evaluations performed by mental health professionals." He speculates that a principal driver of this great challenge is the unknowable contingencies of life. Will a person's spouse leave or will the person lose his or her job or home? As a consequence, will the person return to drinking, stop taking medication, or reconnect with friends who have continued to engage in criminal behaviors? At best, predictive assessments can lead to general statements of probability of particular outcomes, with an acknowledgment of the uncertainties involved.

"The contingencies of life" will place an upper limit on what can be achieved in many risk assessment settings—especially those that approach risk assessment as a one-time

diagnostic enterprise that focuses on individual characteristics. The upper limit may prove to be somewhat higher than it is now if contingencies and contextual factors are systematically embedded in risk appraisals and appraisals are updated over time (Mulvey and Lidz 1995; see also Dickson et al. 2013; Kroner et al. 2013).

There are other promising candidates for incremental advances in violence risk assessment. These include violent victimization (Sadeh et al. 2013), implicit measures (Nock et al. 2010), patient self-perceptions (Skeem et al. 2013), and the incorporation of risk factors from the neurosciences (Aharonia et al. 2013; Poldrack 2013).

If we are approaching a "sound barrier" in the *risk assessment* domain (Coid et al. 2011), there clearly are miles to go before we can rest on the *risk reduction* front. We hope that in the future psychology and psychiatry shift more of their empirical attention from predicting violence to understanding its causes and preventing its (re)occurrence.

SUMMARY KEY POINTS

- Laws regulating the process of violence risk assessment have become more developed over recent years. Increasingly, risk assessment tools are being applied in response to statutes and regulations that require specialized assessments to characterize individuals' risk of violence.
- Risk assessment tools may be aligned along a *continuum of rule-based structure*, with completely unstructured ("clinical") assessment occupying one pole of the continuum, completely structured ("actuarial") assessment occupying the other pole, and several forms of partially structured assessment lying between the two.
- Despite variation among tools, there is little evidence that one validated instrument predicts violence significantly better than another.
- Although some argue that empirically based risk assessments are too inaccurate to be useful in individual cases, we believe that group data theoretically can be, and in many areas empirically are, highly informative when making decisions about individuals.
- All types of risk factors (fixed markers, variable markers, variable risk factors, and causal risk factors) are relevant to *risk assessment,* but only causal risk factors are relevant to *risk reduction.* This is rarely recognized in current discourse, where imprecise terminology abounds. Treatment-relevant risk factors are causal risk factors—and little is known about them. Variable risk factors—despite their clear limitations—are the best the field currently has to offer, to guide risk monitoring and reduction efforts.
- Given a pool of well-validated tools, the choice among them should be driven by the ultimate purpose of the evaluation. If the ultimate purpose is to characterize an individual's likelihood of future violence relative to other people, then choose the most efficient instrument available. If the ultimate purpose is to manage or reduce an individual's risk, then value may be added by choosing an instrument that includes variable risk factors.
- The violence risk assessment field may be reaching a point of diminishing returns in instrument development. Future efforts should shift focus from predicting violence to understanding its causes and preventing its (re)occurrence.

Sex offender risk assessment

AMY PHENIX

EVALUATION OF SEXUAL OFFENDERS

Evolution of contemporary risk assessment

Sex offender commitment laws are not new in the United States. The nation's sexual psychopath laws from the early twentieth century required that psychiatrists make a determination of whether or not an individual met often vague criteria based solely on clinical judgment. Although most of these sexual psychopath statutes have been overturned or repealed, the sexually violent predator laws of the 1990s require that clinicians determine risk of re-offending as one component for commitment. Findings from the classic Hanson and Bussiere meta-analysis (1998) identified static or historical risk factors that predicted sexual re-offense, which allowed for the development of actuarial instruments. These instruments evidenced improved predictive accuracy over clinical judgments regarding sex offender risk. Increasingly, courts are requiring these actuarial instruments when making decisions about the civil commitment of sex offenders.

As with violence risk assessment, three generations of risk assessment for sexual offenders can be identified. The first involved unstructured methods not based on empirical data. Unfortunately, this method's accuracy was no better than chance, and clinicians were wrong as often as they were right. Today it is broadly accepted that evaluations based on unstructured professional judgment are not as accurate as structured risk assessments (Janus and Prentky 2003; Andrews et al. 2006; Quinsey et al. 2006; Monahan 2007). In the late 1990s the second generation of risk assessment evolved with the creation of actuarial risk scales composed of static, historical factors (Bonta and Wormith 2007). The third generation of risk assessment involves the evaluation of dynamic needs, identifying risk factors amenable to change. These dynamic risk factors, also called long-term vulnerabilities or psychological risk factors, have been incorporated into structured instruments to assess relevant risk factors for sexual re-offending (e.g., Fernandez et al. 2012; Helmus et al. 2012a; McGrath et al. 2012).

Currently, the question is not whether risk assessments should be completed for sex offenders, but what methodology should be used. To evaluate this question Hanson and Morton-Bourgon (2009), using meta-analyses, examined 118 studies to determine the accuracy of each method of prediction. For all outcomes, the actuarial method was superior (Cohen's $d = 0.67$ [a measure of the strength of the effect]). Unstructured professional judgment was significantly less accurate than actuarial methods ($d = 0.42$). The accuracy of structured professional judgment was slightly better than unstructured professional judgment ($d = 0.46$). It is now standard practice to use one or more actuarial instruments to evaluate static, or historical, risk factors, which rarely change and provide a baseline of risk for a sexual offender. These data suggest that contemporary risk assessment should include the use of validated actuarial instruments as well as a structured review of relevant dynamic risk factors. In this chapter, the development of current sex offender risk assessments is discussed, including information on reliability and validity as available, and guidelines for how to conduct a comprehensive sexual offender risk assessment are provided.

DETERMINING RISK OF SEXUALLY OFFENDING: ACTUARIAL INSTRUMENTS

The most commonly used and best validated actuarial measures for assessing sexual recidivism risk are the Static-99R and the Static-2002R (Hanson and Thornton 2000; Hanson et al. 2010). Following is a discussion of the development of these instruments.

Static-99 and Static-99R

The Static-99 was developed by Karl Hanson and David Thornton (2000) to assess risk of sexual and violent recidivism with sexual offenders. The Static-99's historical risk factors were derived from earlier tools, the Rapid Risk Assessment for Sex Offender Recidivism (RRASOR) and the Structured Anchored Clinical Judgment (SACJ-Min;

Grubin 1998; Hanson and Bussiere 1998; Hanson and Thornton 2000). The Static-99 measures the risk of sexual or violent reconviction. Because most sex offenses go undetected, the resulting risk estimates should be considered an underestimate of the true risk of recidivism (Bonta and Hanson 1994). The 10-item Static-99 included variables such as prior offenses, prior convictions (both sexual and nonsexual), and characteristics of the victim(s) as well as the offender. The original Static-99 has had over 65 validations on a wide variety of samples and in different jurisdictions (Helmus 2009).

STATIC-99R DEVELOPMENT AND VALIDATION SAMPLES

The Static-99 Revised (Static-99R) was released for clinical use in 2009 (Hanson et al. 2009; Helmus et al. 2012b). The Static-99 was revised for two reasons. First, the Static-99 did not adequately account for reductions in recidivism with advancing age at release (Hanson 2002; Helmus et al. 2012b). Second, more contemporary samples showed substantially lower base rates of sexual recidivism compared to those in the Static-99 development samples. The Static-99R development team has recommended the Static-99R replace the use of Static-99. The Static-99R (Helmus et al. 2012b) was developed and validated with 24 samples drawn from eight different countries. Eleven samples were from Canada, six were from the United States, two were from the United Kingdom, and one each was drawn from Austria, Denmark, Germany, Sweden, and New Zealand. A total of 8390 sexual offenders were included in these samples. For recoding age at release, the sample was divided into construction and validation subsamples. All offenders with a follow-up period less than 10 years were included in the construction sample ($n = 5714$). Offenders with a longer follow-up period were included in the validation sample ($n = 2392$). The entire sample was used to re-norm the Static-99R and to analyze variability of sexual recidivism base rates across the samples. Details of the samples are available in Helmus et al. (2012b). As noted previously, the only change in the Static-99R was the age at release item. Analyses indicated age was not fully accounted for in Static-99; as such, the age item was revised to include four age categories with decreasing risk points for increased age (Helmus et al. 2012b). This new scoring reflects increased risk for younger offenders and decreased risk with advancing age.

VALIDITY OF THE STATIC-99R

The accuracy of the risk assessment in the validation sample (AUC of 0.72) was statistically significant but only nominally higher than that for the Static-99 (AUC = 0.71; Helmus et al. 2012b). In a separate cross-validation of the Static-99R in California, Hanson et al. (2014) reported high relative risk validity (discrimination) and good absolute risk validity (calibration) in a prospective field study of 475 randomly selected adult males released from California prisons in 2006–2007 and followed for 5 years. The resulting AUC = 0.817 (95% CI 0.716–0.919) demonstrated strong relative predictive accuracy.

Ethnic variability was examined by Hanson et al. (2014) in a 5-year follow-up study. The predictive accuracy was statistically significant ($p < 0.05$) for Blacks and Whites, but not for Hispanics (Black [AUC = 0.765], Hispanic [AUC = 0.734], and White [AUC = 0.850]. That nonsignificant finding was at least in part due to the small sample size of Hispanic sexual recidivists ($n = 5$). Logistic regression equations for Black, Hispanic, and White sexual offenders revealed no significant differences in the adjusted base rate (predicted value for a Static-99R score of 2) or in the rate of change in relative risk for a one-unit increase in Static-99R score. Performance of the Static-99R with Black, Latino, and White sexual offenders was also examined in a large Texas study (Varela et al. 2013). The Static-99R did not perform well overall in this study, but its sexual recidivism predictive accuracy for relative risk was similar with Blacks (AUC = 0.65), Latinos (AUC = 0.57), and Whites (AUC = 0.59). Only the AUC for Blacks was statistically significant. In a sample of 319 Canadian Aboriginals and 1269 Canadian non-Aboriginals across five independent samples, Babchishin et al. (2012) found similar, statistically significant levels of predictive accuracy for the Static-99R with both groups, AUC = 0.698 and AUC = 0.726, respectively. However, with a smaller sample of Australian Aboriginals ($n = 67$) and non-Aboriginals ($n = 399$) and a relatively short follow-up period ($M = 29$ months), Smallbone and Rallings (2013) reported statistically significant sexual recidivism predictive accuracy for the Static-99R with Australian non-Aboriginal sexual offenders (AUC = 0.79) but not for Australian Aboriginal sexual offenders (AUC = 0.61). These results indicate that the variability of results based on ethnicity of the sample should be a consideration when using the Static-99R.

In 2015, new norms were released for the Static-99R that included two groups: larger routine correctional samples and high-risk/high-needs samples. The *Routine Norms* are based on correctional samples composed of sexual offenders selected at random. The *High-Risk/High-Needs Norms* are based on sexual offenders selected on the basis of perceived risk for relatively "rare or infrequent measures or interventions or sanctions, such as psychiatric commitments and being held past their release date" (Hanson et al. 2009; Phenix et al. 2012). The routine norms group has the lowest recidivism rates for scores under 7 on the Static-99R. For a score of 7 and above, the two normative groups merge, having similar probabilities of sexual reconviction.

Recent research confirms that the variability in sexual recidivism base rates in the Static-99R samples is due to differences in the presence of unmeasured risk factors external to Static-99R (Hanson and Thornton 2012). These external risk factors are often referred to as long-term vulnerabilities, psychological needs, or dynamic risk factors. Offenders with low to moderate dynamic needs are most similar to offenders in the routine norms; offenders with high dynamic needs are most similar to offenders in the high-risk/high-needs norms. Sexual offenders with identical scores on the

Static-99R have different rates of sexual recidivism based on the density of dynamic needs, with the higher-needs group exhibiting greater rates of sexual recidivism (Hanson and Thornton 2012; Thornton and Knight 2013). Clearly, evaluating dynamic risk factors is necessary when conducting a comprehensive sex offender risk assessment. Measures to assess these needs will be discussed later in this chapter.

RELIABILITY OF THE STATIC-99R

Hanson et al. (2014) assessed the reliability of Static-99R scores from 55 corrections and probation officers in California scoring 14 actual redacted parole cases. Overall inter-rater reliability was acceptable (ICC = 0.78). There was a substantial difference in the reliability of scores from experienced scorers (ICC = 0.85) and less-experienced scorers (ICC = 0.71), pointing to the importance of recent practice. Experienced scorers were defined as those who had scored 26 or more sexual offenders on the Static-99R in the previous 12 months. McGrath, Lasher, and Cumming (2012) reported very high reliability for the Static-99R (ICC = 0.89).

Static-2002 and Static-2002R

The Static-2002 was developed by Hanson and Thornton (2003) to create a risk assessment tool with improved predictive accuracy, conceptual clarity, and coherence. Like Static-99, the Static-2002 was designed to be a brief actuarial measure of relative and absolute risk for sexual recidivism that could be scored from commonly available information in correctional files.

The Static-2002 Revised (Static-2002R) was developed to better reflect decreasing risk with advancing age and to adjust for decreasing base rates of sexual recidivism and variability in those base rates in generating absolute risk estimates. The analyses and results were similar to those reported earlier for the Static-99R (Helmus et al. 2012a,b). The differences between the Static-99R and Static-2002R analyses and results are described here.

Static-2002R was developed on only seven available samples ($n = 2609$) compared to the larger number of samples for Static-99R. With these seven samples, the relative predictive validity for 5-year sexual recidivism was slightly higher on Static-2002R (AUC = 0.713) than the Static-2002 (AUC = 0.709). As with other actuarial tools, relative risk can be reported as nominal risk categories, percentiles, or relative risk ratios. Currently the Static-2002R has the same two normative groups as Static-99R, *Routine Norms* and *High-Risk/High-Needs Norms*.

RELIABILITY

Five studies reporting inter-rater reliability for the Static-2002 scores have been conducted, and all reported high indices of reliability (Haag 2005; Knight and Thornton 2007; Langton et al. 2007; Bengtson 2008). There are no published reports of reliability for the Static-2002R, although the only difference between the two is the age item.

CROSS-VALIDATIONS

Hanson et al. (2010) performed meta-analyses on samples from eight studies ($n = 3034$), both published and unpublished, to assess the predictive accuracy of the Static-2002 in comparison to the Static-99. Across the eight studies, the AUCs for sexual recidivism ranged from 0.64 to 0.79, and all 95% CIs excluded 0.50, reflecting statistically significant predictive accuracy in each of the studies. A similar pattern was evident for violent recidivism. (AUCs ranged from 0.64 to 0.77, and all were statistically significant.) Across all eight studies, the predictive accuracy for sexual recidivism was slightly higher for the Static-2002 (AUC = 0.685) than the Static-99 (AUC = 0.665), differences that were statistically significant. Babchishin et al. (2012) compared the predictive accuracy of the RRASOR, Static-99R, and Static-2002R for 7491 offenders (20 samples from the Static-99R re-norming project) primarily from Canada and the United States. Total scores of Static-2002R (AUC = 0.686) predicted sexual recidivism, similar to that for the Static-99R (AUC = 0.684). In a recent meta-analysis (Tully et al. 2013) of 43 studies and 31,426 sexual offenders, all of the reviewed tools produced at least a moderate effect size in predicting sexual re-offense including the Static-2002 (AUC = 0.70) and the Static-99 (AUC = 0.69).

Babchishin et al. (2012) examined the predictive accuracy of the Static-2002 and the Static-2002R with three samples of Canadian Aboriginals ($n = 209$) and non-Aboriginals ($n = 955$). Predictive accuracy for sexual recidivism was statistically significant in the total sample for the Static-2002 (AUC = 0.740) and the Static-2002R (AUC = 0.733) and in the non-Aboriginal sample for the Static-2002 (AUC = 0.763) and the Static-2002R (AUC = 0.759). In contrast to the Static-99 and Static-99R, there was a significant decrease in predictive accuracy in the Aboriginal sample for both the Static-2002 (AUC = 0.617) and the Static-2002R (AUC = 0.608), though the accuracy for the Static-2002 remained statistically significant.

Use of multiple actuarial instruments

The incremental validity of risk instruments is key to deciding what combination of instruments to use. Incremental validity is defined as the extent to which new information improves the accuracy of a prediction above and beyond that of the previous instrument(s) used.

Seto (2005) examined the incremental validity of several commonly used scales (i.e., RRASOR, Static-99, SORAG, and VRAG) and found the scales did not add incrementally to each other in the prediction of sexual recidivism. Evaluators were advised to choose the "best" instrument, the RRASOR. However, this study was limited by a small sample size. Babchishin et al. (2012) examined the incremental validity of the RRASOR, Static-99R, and Static-2002R in a large cohort of 7491 sex offenders from 20 samples in the Static-99 re-norming project. Contrary to Seto's (2005) prior findings, all three scales provided incremental validity

to the prediction of sexual recidivism, despite the similarity in items on the scales. Decision rules for combining static, actuarial risk instruments for sexual offenders in the overall evaluation of risk were examined by Lehmann et al. (2013). In this study, the RRASOR, Static-99R, and Static-2002R all predicted sexual recidivism (AUCs of 0.69 to 0.71) and provided incremental validity to each other. The authors examined whether choosing the highest, the lowest, or averaging absolute risk estimates (probabilities) optimized accuracy. Their findings supported averaging the probabilities obtained on Static-99R and Static-2002R for the follow-up period of interest (5 or 10 years) for the best absolute estimate of risk to re-offend. In light of recent research on the use of multiple instruments, it is not necessary to choose between them, unless time or resources limit options to one or the other, because risk estimates may be more accurate if they are averaged across the two tools.

Regardless of which tool(s) is used, a number of best practices have emerged from the evolving work on developing actuarial instruments. The first is that relative risk should always be reported because it is consistently stable over time, as reflected in various temporal cohorts. Relative risk should be presented in multiple ways, including nominal risk categories (low, medium, and high rankings), percentiles, and relative risk ratios when available. In some cases, particularly high-stakes evaluations such as sexually violent predator (SVP) and sexually dangerous person (SDP), absolute risk estimates are informative and they should be based on contemporary local norms, if available, and/or the appropriate contemporary norm group estimates provided by the authors. Historically, for Static-99R and Static-2002R some degree of clinical judgment was required in determining which norm group is most appropriate for an individual offender based on the degree of pre-selection for treatment and/or high-risk/high-needs interventions. More recent research has allowed cutoffs on measures of dynamic risk factors/needs to inform the selection of the appropriate normative group. Research on the three actuarial instruments discussed in this chapter is ongoing. As such, normative information and recommendations may change. Thus, professionals using the Static tools should periodically check the static99.org website to ensure that current normative information and language is being used and that they are using the most appropriate methods for selecting absolute risk norm groups.

PSYCHOLOGICALLY MEANINGFUL RISK FACTORS (DYNAMIC RISK FACTORS)

Although the static risk factors have long been established, the changeable risk factors that predict sexual re-offense have been subject to more recent research (Mann et al. 2010). Psychologically meaningful risk factors, also called dynamic risk factors and long-term vulnerabilities, are frequently the targets of treatment because of their amenability to interventions that presumably will decrease risk. Assessment of these risk factors is an integral part of a contemporary risk assessment. Although static risk cannot change, dynamic risk can lower overall risk. Although there are many single sample studies identifying potential changeable risk factors, the Mann et al. (2010) meta-analysis categorized potential risk factors according to the strength of the evidence of their relationship with offending. This group made recommendations for which factors to use in current risk assessments.

Like static risk factors for sexual re-offense, many of the dynamic risk factors have low to moderate effect sizes, so evaluating them collectively will increase predictive accuracy. Currently there are four validated instruments that have been developed to assess psychologically meaningful risk factors in a structured way.

Stable-2007

The Stable-2007 measures sex offender risk factors that are changeable over time and can be used to formulate case management and identify treatment/supervision targets. This instrument can also inform treatment providers and supervision officers when offenders are becoming more or less dangerous over time. Because the Stable-2007 was developed and validated on a community sample, it is the most appropriate instrument to be used for offenders on community supervision.

The Stable-2007 is an outgrowth of the Dynamic Predictors Project (DPP; Hanson and Harris 1998) which included a retrospective file review and interviews with probation, police, and parole officers supervising sexual offenders in the community. The DPP identified a list of the most likely dynamic risk factors, which was used to create the Stable-2007's predecessors, the Sex Offender Need Assessment Rating (SONAR, Hanson and Harris 2000), the STABLE-2000, and the ACUTE-2000 (Hanson and Harris 2004). The Dynamic Supervision Project (DSP) was launched to develop an instrument on prospective data. The DSP followed approximately 1000 sexual offenders in Canada for an average of 43 months. Community supervision officers and law enforcement were trained in risk assessment instruments (Static-99, STABLE-2000, ACUTE-2000) and followed offenders on their caseload until the offenders recidivated or the study period ended. The officers were instructed to score the Static-99 once at the beginning of the project, the Stable-2000 every 6 months, and the ACUTE-2000 every supervision visit. Data were collected across Canada and in the states of Iowa and Alaska (Hanson et al. 2007). These data informed the revision from STABLE-2000 to Stable-2007. The Stable-2007 contains five categories of risk factors; three of the items have multiple factors. The items on Stable-2007 include (1) significant social influences, (2) intimacy deficits, (3) sexual self-regulation, (4) general self-regulation, and (5) cooperation with supervision.

Inter-rater reliability was measured for the Stable-2007 in a maximum security penitentiary (Fernandez 2008) and resulted in an ICC of 0.92 for the total score on the

Stable-2007. The Stable-2007 was cross-validated by Eher et al. (2012) who found that Stable-2007 was significantly related to sexual recidivism, violent recidivism, and general re-offense (AUC of 0.67–0.71). However, in this small sample of 261 rapists and child molesters, the Stable-2007 did not add incrementally above the Static-99. In a subsequent validation by Eher et al. (2013) with a larger sample ($n = 370$) incremental validity was found for the Stable-2007.

Structured risk assessment-forensic version (SRA-FV)

The SRA-FV was developed by David Thornton on a sample from the Massachusetts Treatment Center (MTC, Thornton and Knight 2013). This instrument was developed and validated on incarcerated offenders from the former sexual psychopath program in Massachusetts. As such, it is particularly suited for SVP/SDP evaluations and evaluations on high-risk sex offenders in adversarial conditions. The SRA-FV is based on previous research using the SRA framework (Thornton 2002). According to Thornton's Structured Risk Assessment (SRA), long-term risk factors can be divided into static risk indicators and enduring psychological risk factors that he refers to as *needs* or *long-term vulnerabilities*. The SRA model proposes that these long-term vulnerabilities can be organized into four domains: sexual interests, distorted attitudes, relational style, and self-management. The SRA-FV Need Assessment contains three of the four domains identified in the SRA framework. It has items measuring sexual interests, relational style, and self-management. Distorted attitudes were omitted, as it is difficult to measure such attitudes in adversarial circumstances when offenders may be inclined to provide a socially appropriate response, despite their true beliefs.

All offenders in the construction and cross-validation samples were sexual offenders who had been evaluated between 1959 and 1984 at the Massachusetts Treatment Center for Sexually Dangerous Persons in Bridgewater, Massachusetts, and released from MTC in or before 1984. The instrument was developed on 93–96 offenders and cross-validated on 365–444 offenders with five or more years follow-up. The validation produced an AUC for a 5-year follow-up of 0.72 which was unchanged at a 10-year follow-up.

The SRA-FV has a comprehensive coding manual (Version 1.55) that provides directions to score each item 0 (absent), 1 (some presence), and 2 (fully present). Additionally, the total score on SRA-FV can be used to select the appropriate norms for Static-99R, another advantage for SVP/SDP evaluations

Violence risk scale-sexual offender version (VRS-SO)

The VRS-SO (Olver et al. 2007) is a rating scale designed to assess risk and predict sexual recidivism, to measure and link treatment changes to sexual recidivism, and inform the delivery of sexual offender treatment. The VRS-SO assesses and measures change in treatment by using a modified application of the transtheoretical "model of change" (TTM). The TTM presumes that individuals in sex offender treatment progress through a series of stages known as precontemplation, contemplation, preparation, action, and maintenance, stages that are measured by VRS-SO.

The instrument was developed on 321 male federal Canadian offenders who had participated in a high-intensity sex offender treatment program at a maximum-security forensic mental health facility in Canada between 1983 and 1997. The VRS-SO is modeled closely after the Violence Risk Scale (Wong and Gordon 2006), which is designed to assess nonsexual violence risk and needs. The VRS-SO is a 24-item scale comprising 7 static and 17 dynamic items. The static items were developed with statistical–actuarial procedures on a randomly selected approximately half of the sample ($n = 152$) and cross-validated on the remaining portion of the sample ($n = 169$). A collection of 24 static variables identified from the literature were initially coded and correlated with sexual recidivism. Items with the strongest univariate relationships to outcome were retained and rescaled to a four-point scoring format. The static items can be summed to derive a total risk score. The dynamic items were developed through a review of sex offender prediction and treatment literature.

The dynamic items are potentially changeable by varying degrees. Change on the dynamic items is assessed and quantified through the assessment of a modified TTM. Each of the five stages of change has been operationalized for each of the 17 dynamic items. The advancement in the stages of change (e.g., from contemplation at pretreatment to action at post-treatment) provides evidence of the extent to which the offender has developed positive coping skills and abilities with respect to each dynamic factor. Baseline ratings and ratings as the offender progresses through treatment provide an assessment of positive treatment progress. A factor analysis of the dynamic items of VRS-SO revealed three factors labeled Sexual Deviance, Criminality, and Treatment Responsivity. Inter-rater reliability for VRS-SO for the dynamic items was assessed on 35 randomly selected cases and produced an ICC of 0.74 for pretreatment dynamic items and 0.79 for post-treatment dynamic items. After a 10-year follow-up, predictive accuracy of the VRS-SO static factors was 0.74; for pretreatment dynamic factors, 0.66; and for dynamic post-treatment items, 0.67. The extent to which the dynamic items made unique contributions to the prediction of sexual recidivism after Static-99 and the static items of the VRS-SO were controlled for was examined through Cox regression survival analysis. Significant independent contributions were made by the VRS-SO static item total and dynamic item total. Independent contributions were also observed when these analyses were repeated for Static-99 and the dynamic items, indicating the total dynamic score made significant incremental contributions to predicting sexual recidivism above that of the Static-99.

The VRS-SO has been subject to one independent cross-validation by Beggs and Grace (2010) on a sample of 218 child molesters who received treatment at a prison-based program in New Zealand. The VRS-SO showed good inter-rater reliability for 23 cases on pretreatment scores (ICC = 0.90) and for post-treatment items (ICC = 0.92) concurrent validity and high predictive accuracy for the static and dynamic risk factors both pre- and post-treatment. (AUCs = 0.70–0.81). The dynamic scale made significant incremental contributions after controlling for static risk. The manual provides measures of relative risk (Low, Moderate–Low, Moderate–High, and High) and absolute probabilities of sexual re-offense for the four risk groups at 3, 5, and 10 years.

SEX OFFENDER TREATMENT AND INTERVENTION PROGRESS SCALE (SOTIPS)

McGrath et al. (2012) developed SOTIPS, a new rating scale to assess dynamic risk among adult male sex offenders. SOTIPS predicted sexual, violent, and any criminal recidivism, as well as returns to prison, across time. However, combined SOTIPS and Static-99R scores predicted all recidivism types better than either instrument alone. These results bolster previous sexual offender studies examining the incremental validity of layering assessments of dynamic risk factors onto assessments of static risk factors (Hanson et al. 2007; Knight and Thornton 2007; Olver et al. 2007; Beggs and Grace 2010; Thornton and Knight 2013). These findings collectively indicate that a comprehensive risk assessment should include multiple actuarial instruments, including measures of both static and dynamic risk factors. This practice can also make the selection of Static-99R and Static-2002R norms more empirically based.

ADDITIONAL RISK FACTORS NOT CONTAINED IN STRUCTURED RISK ASSESSMENT INSTRUMENTS

There are no actuarial instruments or measures that assess dynamic risk factors that include all known risk factors for sexual re-offense. Consequently, there are several empirically supported or logically inferred risk factors to consider in overall risk. A contemporary risk assessment should consider psychopathy (as measured on the Hare Psychopathy Checklist Revised, Hare 2003), advanced age, level of community supervision, and sex offender treatment completion and treatment drop out.

SUMMARY

Contemporary risk assessment for sex offender evaluations should include the use of multiple validated actuarial instruments and the most appropriate validated dynamic risk assessment instrument as outlined in this chapter. Evaluators need to avail themselves of formal training prior to use of these instruments to ensure the reliability and validity of scores. Because these instruments do not contain all relevant risk factors and contextual factors, additional empirically related factors may be considered. Risk assessment should be individualized to the offender although the evaluator is discouraged from overriding empirically validated assessments with risk factors not related to sexual recidivism. Finally, evaluators are encouraged to remain current on the research that supports instruments they use and on new, evolving research that informs sex offender risk assessment. As with all of the static and dynamic instruments, the evaluator is advised to participate in formal training before using the instruments.

SUMMARY KEY POINTS

- Actuarial instruments are superior to unstructured clinical judgment when evaluating sex offender risk.
- The use of multiple actuarial instruments can provide enhanced predictive ability.
- Relative risk is stable over time and should be reported as nominal risk categories and percentiles.
- Instruments that assess dynamic risk factors are critical in determining the appropriate normative group and can also be used to develop treatment interventions aimed at risk reduction.
- Sex offender risk assessment should be individualized, but should not rely on idiosyncratic factors unrelated to sexual recidivism.

Structured approaches to assessing malingering

MICHAEL J. VITACCO AND HOLLY E. TABERNIK

INTRODUCTION

The consideration and evaluation of malingering is one of the cornerstones of forensic evaluations. Rendering an accurate opinion and appropriately evaluating the examinee often require an investigation into the possibility the examinee is feigning a disability or deficit for the purposes of gaining an external inducement. The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*; American Psychiatric Association [APA] 2013) defines malingering as the "intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs" (p. 726). The *DSM-5* acknowledges that malingering may be viewed as adaptive in certain circumstances. Beyond a clinical diagnosis used to describe behavior, some jurisdictions and courts consider malingering to be a criminal behavior. For example, the Uniform Code of Military Justice (UCMJ) Article 115 indicates any person malingering for the purpose of avoiding work, duty, or service can be subject to a court martial. In *United States v. Greer* (1998) the Fifth Circuit Court of Appeals held it was constitutional to enhance Mr. Greer's sentence due to obstruction of justice after it was concluded he was continually malingering in an attempt to avoid trial (see Knoll and Resnick 1999). It should be pointed out that Mr. Greer was provided an abundance of opportunities to modify his behavior before "earning" his sentence enhancement.

As this background demonstrates, the accurate assessment of malingering-related response styles is critical. False positives can result in individuals with bona fide mental illnesses proceeding to trial before they receive appropriate mental health treatment. Additionally, false positives can and often do result in bona fide mental health symptoms continuing unabated due to clinicians' reticence to treat symptoms viewed as potentially fabricated. False negatives result in the unnecessary allocation of scarce mental health resources to individuals more interested in avoiding trial or improperly gaining financial compensation, who may not be in need of the treatment provided. Given the ramifications associated with a diagnosis of malingering, its accurate assessment is of paramount importance to ensure just legal findings across judicial proceedings. To that end, forensic mental health professionals have an ethical responsibility to rely on the most reliable and valid methodologies available in order to provide accurate information to the trier of fact.

One such methodology is clinical judgment, whereby clinicians rely on their experience, which can be extensive, in evaluating the veracity of an evaluee's self-report. Bell and Mellor (2009) described several errors accompanying clinical judgment, including misuse of heuristics, potential clinician biases, limitations of information processing, and overemphasis of data obtained during clinical interviews. Unfortunately, clinicians relying on such impressionistic data are prone to committing more errors, regardless of the referral question or the scientific domain. As presented by Dawes, Faust, and Meehl (1989) actuarial methods are superior to clinical judgment. Thus, it should come as no surprise that, when it comes to accuracy, actuarial methodologies yield Cohen's *d*s, a measure of differences between two means, approximately 0.12 higher than decisions based strictly on clinical judgment (Spengler 2013). We believe that given the evidence outlining the strength of instrumentation over clinical judgment in clinical sciences, forensic mental health practitioners should rely on empirically based instruments when considering feigning/malingering.

The use of structured instruments provides another advantage for mental health practitioners. The *Frye* standard relies on determining whether a technique has gained "general acceptance" in the field, which is often predicated on peer review publication. The *Daubert* standard is more sophisticated in its approach to evidentiary admissibility, and provides four prongs. Those prongs include (a) determining whether the theory or methodology is testable and falsifiable, (b) if the technique has been subject to peer

review and has achieved some indicia of general acceptance, (c) the known or potential error rate of the test or methodology, and (d) the existence and/or maintenance of standards concerning the test or methodology. Even a cursory review of evidentiary admissibility underscores the legal problem when relying on clinical judgment in determining feigning. Clinical judgment is highly susceptible to *Frye (Frye v. United States* 1923) or *Daubert* (*Daubert v. Merrell* Dow Pharmaceuticals 1993) challenges and clinicians' methodology should be vigorously questioned in court.

The purpose of this chapter is to encourage clinicians to relinquish reliance on clinical judgment when evaluating malingering in an effort to improve accuracy, validity, and defensibility of their diagnoses. In the first part of the chapter we present a comprehensive analysis on how to accurately assess malingering and related-response styles. The second half of the chapter focuses on the strengths and limitations of various structured clinical instruments designed to detect feigning. The chapter concludes with an approach to assessing malingering that relies on multi-methods and review of several data sources.

DSM-5, MALINGERING, AND BEYOND

Clinicians diagnosing malingering rely on the *DSM-5* (APA 2013) suggestions for when to consider malingering. Unfortunately, the newest addition of the manual failed to incorporate relevant research, leaving the same criteria from the last several editions. This limitation is noteworthy given the 80% false positives associated with the *DSM* criteria (Rogers and Vitacco 2002). Even if the *DSM-5* criteria were simply used as a screening tool designed to cue the clinician when a more extensive evaluation was required, this level of error is unacceptable. In the *DSM-5*, three of the four criteria provide no actual information that adds to understanding malingering. For instance, the mere fact that a medicolegal evaluation (i.e., forensic evaluations, disability evaluations) is occurring is not indicative of malingering. A second criterion is the presence of antisocial personality disorder. In criminal forensic work, many individuals we evaluate have lengthy legal histories and warrant this diagnosis. Yet, the proposed relationship between antisocial personality disorder or psychopathy and malingering has not been supported in multiple studies (cf., Gacono et al. 1995; Poythress et al. 2001; Kucharski et al. 2006). Rogers (1990) perceptively noted that the *DSM* criteria for malingering overrelied on criminogenic factors. A third criterion is lack of cooperation with the evaluation procedures. Individuals are uncooperative for multiple reasons, many unrelated to malingering. As seen by a simple analysis, the *DSM* indicators of malingering are ineffectual and provide the clinician meager guidance to understanding the construct.

The final criterion, "Discrepancy between claimed disability and objective findings" may prove useful in diagnosing malingering. The fact that the criteria for when to consider malingering have not fundamentally changed, even though there have been multiple revisions of the *DSM*, represents a failure to integrate relevant empirical strategies proven effective at detecting malingering. Instead of relying solely on the *DSM* to identify malingering, Rogers (1990) proposed empirical criteria for evaluating malingering. These criteria include (a) a pattern of self-reported symptoms that include an unusually high number of rare, blatant, preposterous, or absurd symptoms, or nonselective endorsement of any symptoms in a high number; (b) contrary evidence in the form of collateral interviews (e.g., interviews with an individual who knows the defendant and provides contrary evidence to their presentation), differences in current presentation, and past documentation of presentation, or strong evidence from psychological testing; and (c) evidence that spurious presentation was not merely attention-seeking behavior.

A SYSTEMATIC APPROACH TO ASSESSING MALINGERING: SIX RECOMMENDATIONS

This chapter presents evidence for the inclusion of specific malingering instruments and scales when assessing an examinee's response style. Clinicians should rely on a standard methodology. This type of structured approach to the evaluation provides a manner to safeguard against diagnostic errors that are common in forensic evaluations. Such errors in forensic evaluations include the following:

1. Overreliance on one type of data when formulating a clinical opinion during a forensic evaluation. In our own clinical work, we have frequently encountered forensic reports where the entire clinical opinion was buttressed by the defendant's version of events. This is not to say the defendant's self-report should be ignored. To the contrary, the defendant's self-report and abilities are critical to developing one's opinion; however, this self-report should be evaluated against independent collateral information and observations.
2. Underreliance or failure to use psychological testing, by default, leads to reliance on clinical judgment. Reid (2000) strongly cautioned against using a general clinical interview to detect and report malingering. Reid stated, "Some psychiatrists and psychologists believe that a good interview and sensitive clinician can see through malingering most of the time. That's just not true" (p. 226). As a field, forensic psychology and psychiatry should be opposed to strict reliance on clinical judgment due to its inaccuracy and tendency to lead to idiosyncratic judgments. When ruling out or ruling in malingering, clinicians are advised in the strongest terms to employ empirically based strategies, like those found in structured instruments designed for detecting feigning.
3. Using psychological testing in the absence of collateral information leads to errors in the accurate assessment of malingering. Psychological testing is frequently employed in evaluations of response style, but there are at least two instances where mistakes could be made on

the basis of psychological testing. The first would be to automatically discount malingering when psychological testing is negative for malingering. Savvy evaluees may have studied psychological testing or have been coached by unethical attorneys on how to avoid being detected. The converse is also true in that results consistent with feigning are not dispositive of malingering. Clinicians must consider alternative explanations for positive results on malingering testing. Even if the clinician ultimately concludes his or her examinee is feigning, there must be other factors taken into account in addition to psychological testing. For instance, the lead author has been involved in several cases where psychological testing was consistent with malingering, but collateral information pointed to a factitious disorder.

4. Clinicians must remain cognizant of potential biases that could lead them away from an impartial finding. The process whereby clinicians ignore, either consciously or unconsciously, information that is contrary to their initial hypothesis is a phenomenon known as confirmatory bias. This process leads clinicians to favor information that supports their initial clinical conceptualizations and ignores divergent information. Either way, not considering all the information related to an evaluee's clinical presentation is antithetical to a fair diagnostic conceptualization. One way to avoid confirmatory biases when evaluating response style is to actively search for evidence supporting the opposing view. We posit that in addition to decreasing the likelihood of inaccuracies, this process also improves credibility as a forensic practitioner.
5. Clinicians often err in their conceptualizations about the rarity or commonality of malingering. Clinicians create unneeded and problematic errors when they undertake forensic evaluations with the idea that "everybody lies." Equally problematic are clinicians who never formally diagnose malingering because they associate malingering with labeling someone as nefarious or a liar. We view both approaches as antithetical to empirical, structured approaches of assessment. Failing to accurately diagnose response style interferes with the aim of presenting accurate and impartial information to the court. Presenting accurate information to the court should be one of the primary goals of the forensic clinician, even if this portrays the client in a less than positive light. Clinicians should be mindful that malingering in forensic criminal cases averages between 15% and 18% (Rogers et al. 1998), although some studies have found slightly higher rates of around 21% (Boccaccini et al. 2006; Vitacco et al. 2007). In civil and correctional settings that rate is often substantially higher.
6. Ignoring explanatory models when conceptualizing malingering may reinforce improper decisions to not diagnose malingering. Clinicians may believe that saying an individual is malingering is equivalent to calling them a "liar." The *DSM* considers malingering to stem from criminological processes, which has clear negative connotations. While some individuals malinger for criminological reasons, others may do so for adaptive reasons. For example, a person may malinger in an attempt to receive mental health medications, move to a quieter unit, avoid a military assignment, or avoid an adverse court finding, including the death penalty. Understanding the underlying reason for malingering may remove the stigma associated with the diagnosis, but it does not abdicate the responsibility of the clinician to provide an accurate diagnosis, even one disadvantageous to the evaluee's case.

INSTRUMENTS USED FOR DETECTING MALINGERED PSYCHOPATHOLOGY

This section focuses on the armamentarium designed to detect malingering. To that end, we focus on several classes of measures. The first are traditional psychological measures designed to assess for psychopathology, which also have specialized scales developed to detect malingering and related response styles. For the purposes of this chapter we focus on the Minnesota Multiphasic Personality Inventory-2 Restructured Form (MMPI-2-RF; Ben-Porath and Tellegen 2008) and the Personality Assessment Inventory (PAI; Morey 2007). In addition, clinicians have an array of specialized measures to detect malingering. In this section our focus is on the Miller Forensic Assessment of Symptoms Test (M-FAST; Miller 2001), the Structured Interview of Reported Symptoms-2nd edition (SIRS/SIRS-2; Rogers 2012), and the Structured Inventory of Malingered Symptomatology (SIMS; Windows and Smith 2005). Finally, we focus on two instruments designed to assess malingering as it specifically relates to competency to proceed to trial examinations: the Inventory of Legal Knowledge (ILK; Otto et al. 2010) and the Atypical Presentation Scales from the Evaluation of Competency to Stand Trial (ATP; Rogers et al. 2004). Table 71.1 provides an overview of each of the reviewed instruments.

Minnesota Multiphasic Personality Inventory-2 Restructured Form

The MMPI-2-RF consists of 338 true/false items designed to assess for psychopathology and several scales designed to evaluate response styles, including malingering. As noted by Rogers and colleagues, "the MMPI-2 RF represents a major departure from the MMPI and MMPI-2 in its development of clinical and validity scales" (Rogers et al. 2011, 355). An earlier meta-analysis of the MMPI-2 demonstrated large to very large effect sizes in detecting malingering with scales incorporating endorsement of rare and infrequent symptoms (Rogers et al. 2003). Similar to the original versions of the MMPI, the response style scales of the MMPI-2-RF are designed to identify evaluees endorsing rare and infrequent symptoms at high levels. Scales for detecting malingering include the following: F-r (infrequent responses),

Table 71.1 Summary of feigning instruments

Instrument	Take home messages
MMPI-2 RF	1. The MMPI-2 RF malingering scales are fairly effective at incorporating empirically based strategies into their scales. 2. Clinicians are on the strongest empirical ground when they rely on the Fp-r and F-r scales in detecting feigned mental disorders. 3. Utilizing high cut-scores on the Fp-r and F-r scales (T > 90) leads to minimized false positives.
PAI	1. The NIM scale appears particularly useful in the classification of malingering. 2. Clinicians should not rely on the results of the RDF due to lack of consistent empirical support. 3. The PAI also can be used as an effective screen for malingering when used in conjunction with comprehensive measures of malingering, like the SIRS-2.
SIRS-2	1. The SIRS-2, like the SIRS, utilizes multiple empirically based detection strategies for detecting feigning. 2. For evaluating the feigning of psychosis or other severe psychopathology the SIRS-2 is the premiere instrument, but there appear to be limitations related to indeterminate classification on the SIRS-2. 3. The SIRS-2 should not be used to assess feigning of cognitive disorders, and there appear to be limitations for assessing individuals with significant trauma histories where there is objective evidence of dissociation.
M-FAST	1. The M-FAST produces large effect sizes in both civil and criminal forensic examinations when using the recommended cut-score. 2. Despite its strong psychometric properties, the M-FAST is designed as a screen. Using the M-FAST for something beyond a screen is antithetical to its intended use. 3. Like the SIRS, the M-FAST encompasses multiple detection strategies that appear to work optimally at distinguishing malingered from bona fide psychotic symptoms and other significant psychopathology.
SIMS	1. The SIMS demonstrated the ability to differentiate individuals with bona fide mental illness from those feigning mental illness. 2. The SIMS has a variety of scales, but the ones designed for cognitive feigning have not been as consistently validated. 3. The SIMS, although designed as a comprehensive measure of malingering, likely works best a screen for malingering.
TOMM	1. The TOMM has been normed with both clinical and experimental populations and has strong psychometric properties in the evaluation of cognitive malingering. 2. A below chance score on the TOMM may be indicative of malingering, but scoring below the recommended 45 cut-score warrants additional evaluation. 3. Given the unacceptable likelihood of false positives with individuals functioning in the moderate or severe range of intellectual disability, clinicians should be especially cautious about using the TOMM in these populations.
VIP	1. The VIP is considered groundbreaking because it contains indices measuring both motivation and effort (Denny 2008). 2. The VIP is particularly useful when an individual is claiming cognitive difficulties in the absence of a history of such deficits. 3. The VIP has not been adequately validated on individuals with legitimate cognitive dysfunction. Similar to the TOMM, we do not recommend use of the VIP with individuals with bona fide histories of moderate or severe intellectual disabilities.

Fp-r (infrequent psychopathology responses), Fs (infrequent somatic responses), FBS-r (symptom validity), RBS (response bias), L-r (uncommon virtue), and K-r (adjustment validity).

Research studies have demonstrated the effectiveness of the MMPI-2-RF response-style scales. In an experimental paradigm, undergraduate students were instructed to feign and their results were compared to patients with legitimate psychopathology. Out of the MMPI-2 RF validity scales, the Fp-r scale was the only style scale to demonstrate discriminant validity and to manifest incremental validity compared to the other RF validity scales (Sellbom and Bagby 2010). Sellbom et al. (2010) evaluated the effectiveness of the RF validity scales in a known-groups design using the Structured Interview of Reported Symptoms (SIRS, Rogers et al. 1992) with 125 forensic patients. The Fp-r and the F-r were most successful at differentiating feigners from non-feigners. These scales rely on the presence of rare symptoms to detect atypical responding. As noted by the authors, the Fp-r and F-r scales appear complementary to each other in the accurate detection of feigned presentations. In another known-groups design, Rogers et al. (2011) analyzed the

effectiveness of the RF validity scales in a large sample of individuals ($n = 645$) undergoing disability evaluations. For feigned mental disorders, Fp-r and F-r scales produced very large effect sizes and an extremely low rate of false positives in contrast to individuals with an actual mental disability.

Personality Assessment Inventory

The PAI is a 344-item instrument that is designed to assess general psychopathology. As with the MMPI, the PAI has several scales designed for detecting malingering, including CDF (Cashel's Discriminant Function), NIM (Negative Impression Management), MAL (Malingering Index), and RDF (Rogers Discriminant Function). Additionally, Gaines et al. (2013) developed the MFI (Multiscale Feigning Index) for the PAI. As described by the scale name, this index relies on detecting feigning by considering elevations on several PAI scales. Although the MFI demonstrated good results compared to the SIRS, without cross-validation, clinicians are advised to rely on empirically supported indices of feigning that have undergone extensive cross-validation.

With regard to malingering, the PAI does not have the comprehensive research base as does the MMPI; however, a 2009 meta-analysis completed by Hawes and Boccaccini (2009) reported high effect sizes for malingering scales on the PAI showing differences between individuals classified as malingering compared to individuals' feigning psychopathology. Boccaccini, Murrie, and Duncan (2006) reviewed the ability of the PAI (and MMPI-2) to act as screens for malingering in 166 males undergoing pretrial forensic evaluations under the federal system. Using various cut scores, the authors found the NIM scale possessed the greatest level of accuracy for evaluating malingering; however, the RDF scale performed poorly. In a 2007 study, Hopwood et al. (2007) evaluated the ability of the PAI to detect feigning specific disorders. The NIM scale was effective across diagnostic classifications at ascertaining malingering.

Structured Interview of Reported Symptoms

The SIRS/SIRS-2 (see Rogers et al. 1992, 2010) is a structured clinical interview consisting of 172 items yielding eight primary scales. The eight scales encompass a variety of empirical strategies for detecting feigned presentation. These strategies consist of evaluating for the presence of rare symptoms, combinations of symptoms that do not go together, absurd symptoms, extremely high severity of symptoms, reporting symptoms across multiple diagnostic categories, differences in reported versus observed symptoms, presence of blatant symptoms, and presence of subtle symptoms. Since its publication in 2002, the SIRS has been cited as the most valid and used measure for evaluating feigning (Lally 2003; Archer et al. 2006). Specifically, the SIRS has demonstrated a high level of effectiveness with adolescent (Rogers et al. 1996) and adult offenders (Kucharski and Duncan 2006; Edens et al. 2007), as well as mental health patients (Edens et al. 2007; Vitacco et al. 2007).

The SIRS-2 was developed with the same basic structure as the SIRS, but with added steps to protect against false positives. The reader is advised to refer to the SIRS-2 manual for specifics on the newly developed steps. Yet, these changes have been met with criticism. Two reviews in the Open Access Journal of Forensic Psychology have been critical of the SIRS-2, while still touting some of its psychometric properties (Rubenzer 2010; DeClue 2011). Rubenzer (2010) indicated "the SIRS-2 is a strong choice for assessing feigned psychosis and severe psychopathology" (p. 273). Rubenzer discusses the use of the SIRS-2 for feigning cognitive impairment or somatic complaints, concluding with the recommendation that no single test, including the SIRS-2, should be relied on as a "gold standard." DeClue (2011) reported on potential legal admissibility issues with the SIRS-2, and expressed concern that the raw data from the SIRS-2 were not readily accessible. We concur with the warning proffered by Green et al. (2013), "The limited settings in which the SIRS-2 has been validated, coupled with differences between sensitivity rates observed in the current study versus those published in the manual, raises concerns for both the reliability and validity of the SIRS-2 scoring algorithms" (p. 216). As a final note, the SIRS-2 manual advises against using the instrument with individuals with substantial trauma histories who are actively dissociating.

Miller Forensic Assessment of Symptoms Test

The M-FAST is a structured clinical interview that consists of 25 items that load on seven scales. However, three scales are composed of a single item. Similar to the structure of the SIRS-2, the M-FAST relies on multiple, empirically based detection strategies. These strategies include atypical symptoms, unusual symptom combinations, unusual hallucinations, unusual symptom course, overly negative self-image, susceptibility to endorsing unusual symptoms, and differences in reported versus observed symptoms. However, the M-FAST was designed to be used as a screening tool to identify individuals in need of a more comprehensive evaluation of response styles. As such, when looking at the psychometric properties of screening instruments like the M-FAST, false positives are not only more acceptable, they are expected. In screening instruments, false negatives are much more problematic. If the individual's score does not reach the cut-score on the screen, they are generally ruled out from further assessment and malingering may go undetected. For this reason, most screening tools are designed to minimize false negatives.

The M-FAST appears most adept at detecting the presence of overt feigning (Vitacco et al. 2008). As a screen, the M-FAST has evidenced strong discriminant validity in both civil and forensic evaluations (Guy and Miller 2004; Veazey et al. 2005; Alwes et al. 2008). In a known groups design with pretrial forensic patients, using the SIRS as the classification

standard, the M-FAST produced a strong alpha coefficient (how the items are related to one another) for the total sample and very large effect size between the nonmalingering and malingering groups (Cohen's $d = 2.69$). Using the recommended cut score of 6, the M-FAST produced perfect sensitivity and negative predictive power (Vitacco et al. 2007). Similar results were found for the M-FAST with 308 individuals undergoing evaluation for workers' compensation or disability (Cohen's $d = 3.0$; Alwes et al. 2008).

Structured Inventory of Malingered Symptomatology

The SIMS is a 75-item self-report test designed to evaluate feigning across five diagnostic domains. These domains include Low Intelligence (LI), Affective Disorders (Af), Neurological Impairment (N), Psychosis (P), and Amnesia (Am). Based on the manual, a total score of greater than 14 is suggestive of feigning, and produced an overall correct classification rate of 94.96%. It is important to note the final SIMS sample "was empirically validated at four different universities and community colleges in an analogue simulation study" (p. 12), but the validation samples lacked individuals undergoing forensic evaluations. As such, external validity is lacking due to the use of simulation designs.

The authors of the SIMS primarily relied on nonclinical samples in its initial validation, but several subsequent studies (Lewis et al. 2002; Vitacco et al. 2007; Alwes et al. 2008) have tested the efficacy of the SIMS with clinical populations. In a sample of 64 men undergoing pretrial forensic evaluations, Lewis et al. (2002) used the MMPI-2 and the SIMS as screening tools to assess for feigning. Effect sizes for all SIMS scales ranged from large to very large (*Cohen's ds* ranging from 1.1 to 3.0) between honest responders and feigners. Likewise, Vitacco and colleagues (2007) found very large effect sizes between the nonmalingering and feigning groups (Cohen's *d* ranging from 1.51 to 3.07), but the recommended cut score produced a moderate hit rate (0.72). Additionally, if employed as a screening tool, the SIMS produced strong results with excellent negative predictive power.

Competency-specific malingering instruments

In addition to the broad measures of malingered psychopathology, the Inventory of Legal Knowledge (ILK; Otto et al. 2010) and the Atypical Presentation Scales of the Evaluation of Competency to Stand Trial-Revised (ATP; Rogers et al. 2004) are both designed to detect competency-specific feigning.

The ILK is a 61-item instrument designed "to assist forensic examiners in the assessment of response styles of defendants undergoing evaluations of adjudicative competence" (Otto et al. 2010, 7). The ILK has demonstrated moderate correlations with other measures of malingering (Otto et al. 2011) and evidenced good discrimination in both college students and mental health populations instructed to feign (Guenther and Otto 2010). Yet, there have been concerns about the efficaciousness of the recommended cut-scores (Gottfried and Carbonell 2014a,b), which may be resultant from the relatively high rates of feigning (47%) in the validation sample (p. 19). Based on extant research the ILK has potential as a screening tool in competency to proceed to trial evaluations; however, only scores significantly lower than chance demonstrate feigning. Further research is needed to clarify cut scores on the ILK and test their ability to evaluate feigning.

The ATP scales of the Evaluation of Competency to Stand Trial-Revised (ECST-R, Rogers et al. 2004) are administered to assess for feigned presentation during competency to proceed to trial evaluations. The ATP consists of 28 items specifically crafted to assess for competency-specific impairment. The 28 items load onto three scales (Rational, Psychotic, and Nonpsychotic). In addition there is an Impairment scale and a scale named Both (sum of Psychotic and Nonpsychotic). The items are scored on a three-point scale (no, sometimes, and yes), except for the Impairment Scale, which is scored categorically (no or yes). Two additional scales are created by summing two of the aforementioned scales. For the sake of malingering, the Rational scale is not included, as these are items that represent legitimate concerns shared by most defendants. Two studies have demonstrated the effectiveness of the ATP scales to detect feigning. In a known-groups design (Vitacco et al. 2007), the ATP scales demonstrated very large effect sizes differentiating malingerers from nonmalingerers. In research using both simulation and actual competency cases, Rogers et al. (2004) reported the scales yielded large effect sizes for malingering in both simulation (Cohen's $d = 2.50$) and actual forensic (Cohen's $d = 1.83$) samples.

DETECTING MALINGERED COGNITIVE DEFICITS

In addition to feigning severe psychopathology in order to achieve a desired outcome, forensic mental health practitioners should be aware of the potential for individuals to feign memory or cognitive deficits. For example, individuals who have been charged with serious offenses may feign a head injury, asserting memory deficits that lead to an inability to recall critical aspects of their case. However, even in cases where an individual has actual amnesia, it is not enough to render them not competent to proceed to trial. As noted in *United States v. Wilson* (1966) and *United States v. Andrews* (2006) memory loss needs to be evaluated on a case-by-case basis, and the mere presence of amnesia is not an automatic bar to competency. Nonetheless, the stakes can be extremely high when considering intellectual deficits. For example, a diagnosis of Intellectual Disorder is a barrier to the death penalty (see *Atkins v. Virginia* 2002). Considering response styles in these assessments is critical to support the veracity of the clinician's opinion and reported test findings.

Mental health practitioners have a wide variety of measures at their disposal to evaluate cognitive malingering. In a survey of 188 neuropsychologists, the Test of Memory

Malingering (TOMM; Tombaugh 1996), MMPI-2, Rey 15-item test (Rey 1964), and the California Verbal Learning Test (Delis et al. 2000) were most frequently used to detect malingering; however, the TOMM, Validity Indicator Profile (VIP; Frederick 2003), Victoria Symptom Validity Test (Slick et al. 1997), Word Memory Test (Green 2006), and Computerized Assessment of Response Bias (Allen et al. 2002) were rated as most accurate.

Psychologists using structured approaches for detecting feigned cognitive impairment are encouraged to be aware of the Slick criteria. The Slick criteria consist of a set of criteria clinicians can rely on when making informed decisions on cognitive malingering (Slick et al. 1999). The criteria are relatively straightforward and are as follows: Criterion A: one identifiable, substantial external incentive; Criterion B: evidence from test data; and Criterion C: evidence from self-report. Finally, as a rule out, it is important that the behavior not be fully accounted for by psychological, neurological, or developmental factors.

In considering detection strategies for cognitive malingering, Rogers et al. (1993) set forth some strategies that can be integrated into empirically based measures of this type of malingering, including the following:

- Floor effect is a strategy where individuals who are feigning cognitive deficits miss even the most basic of questions, for instance, an individual with a high school diploma and no history of head injury who indicates he or she is unable to sum one plus one. The floor effect strategy is incorporated in several instruments designed to detect cognitive feigning. These instruments include the Rey 15-item test and the Test of Memory Malingering (TOMM; Tombaugh 1996), and the Hiscock Digit Memory Test (Hiscock and Hiscock 1989).
- Symptom validity testing specifically relies on below-chance levels of responding. This is a strong approach to detecting malingering because an individual who achieves a score significantly below chance has a very strong probability of feigning intellectual impairment. It should be pointed out that below-chance scoring on multiple choice items is highly unusual, as even unsophisticated feigners typically perform at better than chance.
- Forced-choice testing is a broad term that typically refers to achieving less than expected results when having to pick the correct choice from two options. This technique can also be incorporated into both symptom validity testing and floor effect strategies. Forced-choice testing evaluates an individual's performance against individuals with neurocognitive deficits with little motivation to feign (Berry and Schipper 2008). This approach can identify "probable" feigners who require a more in-depth evaluation of their response style.
- Magnitude of error refers to evaluating incorrect responses against what are considered typical responses. Magnitude of error responses refer to atypical and unusual responses, generally not given by individuals with bona fide cognitive disorders. Individuals suspected of feigning are much more likely to select a response with a low probability of occurring as compared to individuals with true impairment (Martin et al. 1998).
- Performance curve is a strategy focusing on which items on a measure are failed. Individuals who are feigning often will routinely miss easy questions, while answering more difficult questions correctly. This strategy is employed in the Validity Indicator Profile (VIP; Frederick 2003), discussed below.

Instruments used to detect cognitive malingering

This section reviews two of the most widely used instruments in the evaluation of cognitive and memory malingering. Given the relatively large number of instruments commercially available (Sweet and King 2002), we focus on two of the most used and validated: the Test of Memory Malingering (TOMM) and the Validity Indicator Profile (VIP).

According to the manual, the "TOMM is a 50-item recognition test for adults that includes two learning trials and a retention trial" (Tombaugh 1996, 1). The individual is shown 50 line drawings, and then presented with 50 cards with two line drawings on each card. The individual is simply asked to pick which of the two drawings he or she saw previously. The TOMM has several strengths; one of the primary strengths of the TOMM is that it is sensitive to malingering; the TOMM, however, is relatively insensitive to neurological and cognitive impairments. Any score below chance is indicative of malingering and a score of lower than 45 on Trial 2 or the retention trial indicates possible malingering. There have been concerns raised about the TOMM's classification of individuals with intellectual disabilities, although the results have been conflicting. The professional manual of the TOMM (see also Simon 2007) reported individuals with lower intellectual functioning score generally above the recommended 45 cut-score; however, Shandera et al. (2010) found individuals with more severe forms of cognitive dysfunction (e.g., moderate mental retardation) scored below the cut-score, and thus would be falsely categorized as malingering. As such, clinicians should be extremely cautious regarding using the TOMM with individuals manifesting moderate to severe intellectual disabilities until subsequent research can provide a more solid foundation for using the TOMM with this unique population.

The VIP is a paper and pencil test designed to detect cognitive malingering. The VIP evaluates consistency of responding as well as overall effort. Invalid profiles fall into one of three categories: (a) poor effort or carelessness, (b) random responding, or (c) malingering, high effort to appear impaired. Consistent with many intellectual tests, the VIP contains both a Verbal and Nonverbal subtest, so effort can be evaluated across both areas. The validation sample consisted of 944 nonclinical participants and

104 adults undergoing neuropsychological evaluation. The cross-validation sample consisted of 152 nonclinical participants, 61 brain-injured adults, 49 individuals considered to be at risk for malingering, and 100 randomly generated VIP protocols (see Frederick et al. 2000). The overall classification accuracy for the nonverbal test was 79.8%, with 73.5% sensitivity and 85.7% specificity. The verbal subtest of the VIP was similar, with an overall classification rate of 75.5%, 67.3% sensitivity, and a specificity rate of 83.1%.

SUMMARY

Structured approaches to evaluating malingering provide significant advantages over clinical judgment. The primary goal of this chapter was to present a structured methodology for appropriately evaluating malingering that goes significantly beyond the basic *DSM* criteria. Moreover, structured approaches to malingering require more than the administration of a malingering test (or several). A structured approach to the evaluation of malingering consists of (a) a close review of records in order to assess previous functioning and make analytic comparisons to current functioning, (b) an evaluation of the veracity of self-report in combination with observations and a review of records, and (c) use of psychological testing to make empirically based comparisons to normative groups. By taking the time to complete this structured step-by-step approach, clinicians place themselves in good position to make accurate statements regarding response style. In addition, by using structured approaches, clinicians are likely to be viewed as more credible when discussing their findings with the trier of fact.

SUMMARY KEY POINTS

- Clinical judgment in the determination of malingering is outdated and results in errors.
- An individual who is malingering may also have a mental illness; careful, structured approaches consider both.
- Forensic examiners should not place too much weight on one data point and instead consider an array of factors when evaluating response styles, like malingering.
- Considering explanatory models of malingering allows the clinician to understand the individual's motive for feigning.
- The evaluation of malingering should remain a cornerstone of forensic evaluations.

Forensic neuropsychology

KYLE BRAUER BOONE

INTRODUCTION

Neuropsychology originally developed in the mid-1900s as a method of using assessment of various cognitive skills to identify which areas of the brain (primarily cortex) were damaged and dysfunctional. That is, language deficits would point to damage to the left hemisphere in most individuals, while dysfunction in visual perceptual/spatial abilities would implicate injury to the right hemisphere. Likewise, losses in verbal versus visual learning and memory would suggest damage to left and right medial temporal lobe structures, respectively. Disturbances in sequencing, problem solving, mental flexibility, multitasking/divided attention, and response inhibition would be consistent with dysfunction of frontal and subfrontal structures. Weaknesses in motor dexterity and strength of the hands/fingers could signal disruption of motor strips of the contralateral hemispheres. However, with advent of sophisticated brain imaging techniques, the use of testing to localize brain damage became less important. Instead, the focus of neuropsychological testing came to emphasize objective quantification of cognitive abnormalities for the prediction of function in daily life activities.

Concurrently, neuropsychological assessment began to be important within civil litigation as a method to document "damages," or losses in function associated with acquired brain injury. The types of cases in which neuropsychologists typically provide assessments in civil injury include traumatic brain injury, medical malpractice, toxic exposures, etc. Concurrently, neuropsychological assessment has assumed a critical role in criminal litigation contexts. Neuropsychologists provide test data relevant to such questions as to whether defendants have the cognitive capacity to understand right and wrong, the impact of their actions on others, societal laws, and their rights as a defendant and whether they are able to meaningfully collaborate with defense counsel. Neuropsychologists are unique in providing carefully quantified data regarding extent of cognitive loss and dysfunction for juries as they make decisions regarding extent of damages and criminal responsibility.

ASSESSMENT OF PERFORMANCE VALIDITY

Neuropsychologists have an obligation to ensure that the data they report to triers of fact accurately reflect a test taker's true level of neurocognitive function. Plaintiffs in a personal injury lawsuit have motive to inflate symptoms and level of dysfunction because this can increase damage awards. Likewise, individuals seeking disability benefits have incentive to feign or exaggerate symptoms because this may enhance compensation amounts. Criminal defendants have motive to feign cognitive deficits in the service of excusing themselves from responsibility for criminal acts, while individuals seeking accommodations for learning difficulties and attention deficit disorder have impetus to feign or exaggerate such disorders to insure they receive extra test administration time or other educational supports.

Neuropsychological assessment reports in the latter half of the 1900s typically would include a statement indicating that test takers appeared to be performing to true ability and that test results were judged to be an accurate reflection of true skill level. However, these assertions were based only on "gut" impressions, and whether these conclusions were accurate was unknown. In retrospect, it is now appreciated that the error rate was likely high. For example, Larrabee et al. (2009) concluded that the average prevalence of noncredible neurocognitive test performance in populations with motive to feign is 40% ± 10%.

Prior to the 1990s, research on techniques to identify noncredible performance on neurocognitive testing was sparse. Since that time there has been an explosion of publications addressing the development and validation of such techniques. Initially the field focused on creating tests that had a single purpose in identifying failure to perform to true ability, so-called "dedicated" or "free-standing" measures (originally referred to as "symptom validity tests" [SVTs], but now termed "performance validity tests" [PVTs] in recognition that test takers are asked to "perform" neurocognitive tasks; the label "SVT" is now used to refer to symptom overreport scales on objective personality inventories, such

as the MMPI-2-RF; Larrabee 2012). However, more recently the field has moved toward validating performance validity techniques derived from standard neurocognitive tests ("embedded" measures) in that this reduces test battery administration length and provides an evaluation of performance validity in "real time" (i.e., during actual administration of standard neurocognitive tests, rather than extrapolating conclusions regarding validity of test scores from dedicated performance validity tests that may have been administered up to hours before or after the other tests). Additionally, the field of neuropsychology is now beginning to appreciate that performance validity is not a "unitary construct," and that test takers can elect to feign at different times during a neuropsychological exam, and in particular skill areas that they think are most impacted by the disorder they are claiming (Boone 2009). In fact, it is atypical for a noncredible test taker to feign on every type of task administered (Boone 2009), reflecting the perception that it would appear implausible if he or she could not perform any tasks. "Embedded" performance validity indicators best allow continuous measurement of performance validity across a neuropsychological exam.

In evaluating the suitability and appropriateness of various performance validity measures, the examiner must consider test *sensitivity* and *specificity*. *Sensitivity* refers to the percentage of noncredible test takers who are correctly identified as noncredible using the technique, while *specificity* refers to the percentage of credible patients who are correctly identified as credible. Test cut-offs are traditionally selected to maintain specificity of at least 90%, reflecting the view within the field that it is particularly important to ensure a low test false-positive rate to protect credible patients from being incorrectly determined to be noncredible. Resulting test sensitivity can be found to be low (<40%), moderate (40%–69%), or high (≥70%). There is likely a ceiling on performance validity test sensitivity because noncredible test takers are hetereogeneous and feign in differing ways. Low to moderately sensitive PVTs can be used to "rule in" noncredible test performance, but cannot be used to "rule out" malingering. That is, a positive finding is highly suspicious for noncredible performance because scores beyond cut-offs are relatively rare in credible populations (i.e., <10% false-positive rate), but a passing score on low to moderately sensitive PVTs is not unusual in noncredible populations; therefore, passing scores cannot necessarily be used to conclude that the test taker was performing to true ability.

Most "dedicated" performance validity tests involve recognition memory, in particular, "forced choice" paradigms in which the test taker is presented with a series of items (primarily words or pictures), and then several trials (often a total of 50) in which each previously seen stimulus is paired with a new stimulus, with test takers instructed to identify which item was previously seen (e.g., Test of Memory Malingering [Tombaugh 1996], Warrington Recognition Memory Test—Words [Bell-Sprinkel et al. 2013], Portland Digit Recognition Test [Binder 1993], Victoria Symptom Validity Test [Slick et al. 1996], Word Memory Test [Green 2005], Medical Symptom Validity Test [Green 2004], and Nonverbal Medical Symptom Validity Test [Green 2008]).

Additional dedicated performance validity tests involve speeded counting (Dot Counting Test; Boone et al. 2002a), rapid letter identification (b Test; Boone et al. 2002b; Roberson et al. 2013), recognition of words in a list (Rey Word Recognition Test; Bell-Sprinkel et al. 2013), and drawing of simple pictured items (e.g., letters, numbers, shapes) and circling of items recognized from a larger array (Rey 15-item plus recognition; Boone et al. 2002c). Dozens of "embedded" performance validity indicators have been validated, and the interested reader is referred to Boone (2007, 2013) and Victor et al. (2013a,b) for listings and discussion.

Current practice recommendations in the field indicate that performance validity measures should be administered throughout the neuropsychological exam (National Academy of Neuropsychology; Bush et al. 2005) and that both dedicated and "embedded" techniques should be employed (American Academy of Clinical Neuropsychology; Heilbronner et al. 2009).

CURRENT CONTROVERSIES REGARDING INTERPRETATION OF DATA FROM MULTIPLE PVTS

Although individual PVT cut-offs are set to allow few false positives, questions have been raised regarding overall specificity rates when multiple PVTs are employed. The concern has been that use of multiple PVTs may raise false-positive rates to well over 10%. However, multiple "real-world" studies of clinical populations have shown that although it is not unusual for credible patients to fail a single PVT, very few fail more than one. For example, Victor et al. (2009) reported that only 5% of their credible sample failed two PVTs (out of four), Schroeder and Marshall (2011) observed that 5%–7% of psychiatric patients failed two PVTs (out of seven), and Larrabee (2003) found that 6% of his credible moderate to severe traumatic brain injury sample failed two validity measures (out of four PVTs/one SVT). Victor et al. (2009) further documented that only 1.5% of their sample failed three PVTs, and zero failed four, while Larrabee (2014a) reported that 4% of his sample failed three measures (out of 6 PVTs/1 SVT), with no false-positive identifications after three failures. Other researchers have documented that two to three PVT failures are associated with 100% specificity (Meyers and Volbrecht 2003; Sollman et al. 2010; Chafetz 2011; Schroeder and Marshall 2011; Davis and Millis 2014a; Meyers et al. 2014). Larrabee (2008) demonstrated that, using posterior probabilities, the probability that a test taker who fails three PVT cut-offs is in fact noncredible is essentially 99%, a finding recently confirmed by Meyers et al. (2014).

Berthelson and colleagues (2013), citing results from a statistical simulation, argued that the false-positive rate for two PVT failures (with cut-offs set to 90% specificity) in a credible population is 11.5%. They concluded that when three PVT failures are required to document performance

invalidity, only eight should be administered, because if more are given, the false-positive rate will rise above 10%. Silk-Eglit and colleagues (2015) subsequently examined false-positive rates in use of multiple "embedded" PVTs, and concluded that to maintain a false-positive rate of ≤10% when analyzing data from 3, 7, 10, 14, and 15 performance validity indicators, noncredible performance would be indicated by failing of ≥1, ≥2, ≥3, ≥4, and ≥5 indicators, respectively.

To check the accuracy of Berthelson et al. (2013) simulation, Davis and Millis (2014a) examined PVT false-positive rates in a neurologic population with no motive to feign impairment, and observed that when six to eight PVTs are administered (with cut-offs set to 90% specificity), the actual occurrence of one or two failures was lower than that predicted by Berthelson et al. (2013). They further documented that there was no significant relationship between number of PVTs administered and number failed ($r = 0.10$). Similarly, Larrabee (2014a), in examining scores in a "real-world" clinical sample, found that the actual occurrence of at least three PVT failures (out of seven) was only 4% (as compared to 7.3% for Berthelson et al.). Larrabee (2014a) suggested that the Berthelson et al. simulation overestimated the rate of multiple PVT failures in credible populations, likely because PVT data do not have normal score distributions required for use of the simulation model.

The Silk-Eglit et al. (2015) examination of false-positive rates with use of multiple embedded PVTs likely also overestimated false-positive rates but for different reasons. All subjects had motive to feign (i.e., were mild traumatic brain injury litigants), and the subjects assigned to the credible group were allowed to fail one PVT; using these criteria, noncredible subjects were likely included in the credible group. Further, some of the PVT cut-offs had lowered sensitivity (e.g., Rey 15-item recall ≤9 = 59% sensitivity, Boone et al. 2002c; TOMM Trial 2 or retention <45 = 48% sensitivity; Greve et al. 2008), additionally raising the likelihood that noncredible test takers were inadvertently assigned to credible group. Also, many of the "embedded" PVT scores were from the same tests; scores from the same test would likely be failed "as a group," falsely giving the appearance that the test taker had failed multiple PVTs. Finally, sample sizes in the Silk-Eglit study were very small (24 credible, 25 noncredible), raising questions regarding the reliability and stability of the findings.

Subsequently, Bilder et al. (2014) raised questions regarding the Larrabee (2014a) and Davis and Millis (2014a) critiques of the Berthelson et al. (2013) study, asserting that research in fact shows an impact of number of PVTs administered on number failed, although the data they provide indicate that failure on three out of up to eight PVTs is associated with an acceptably low false-positive rate (except in patients with severe neurologic compromise and functional limitations). Bilder et al. (2014) also argued that studies that exclude individuals with low IQ and dementia from credible samples artificially lower PVT false-positive rates. The authors appeared to recommend that before data on multiple PVTs can be used clinically, empirical data are needed on various combinations of PVTs because of differing probabilities of joint failure.

Davis and Millis (2014b) responded to the Bilder et al. (2014) paper, highlighting statistical limitations and pointing out that the psychometric standards that Bilder et al. are requiring of PVTs are not met by other neuropsychological instruments. Davis and Millis also noted that the apparent "huge" increase in PVT failures claimed as a function of increasing numbers of PVTs administered is actually small; that is, the predicted number of PVT failures when five are administered is 0.55, and the predicted number failed when nine PVTs are administered is 1.01, which while a "doubling" of error, in absolute numbers represents an increase from one-half to one PVT failed.

Finally, Larrabee (2014b), in critiquing the Bilder et al. (2014) paper, agreed that some patients are falsely identified as noncredible due to failed PVT performances, but research indicates that these false-positive identifications are limited to patients with severe impairment, often requiring supervised living arrangements, such as patients with dementia, moderate to severe traumatic brain injury involving structural brain imaging abnormalities and prolonged coma, stroke with aphasia, mental retardation, and severe psychiatric disturbance. Larrabee argues that in the absence of these conditions, PVT failures would not represent false-positive errors.

A further concern not yet adequately addressed by available literature on interpretation of data from multiple PVTs is the fact that performance validity is not a "unitary" construct and that many noncredible test takers are highly selective regarding the cognitive areas in which they attempt to feign deficits (Boone 2009). For example, a recent personal injury litigant evaluated by this author who was claiming unverified central nervous system (CNS) toxic injury failed four PVTs checking for veracity of performance in processing speed while passing the remaining 11 PVTs assessing for performance validity in memory, attention, visual perception/constructional skill, tapping speed, and sensory function. In another recent case involving a mild traumatic brain injury litigant, the test taker failed 4 of 12 PVTs, but the failures were confined to verbal and visual memory. In the latter case, some of the failed PVT scores were the most extreme ever observed by this examiner. Rather than reflecting "borderline" evidence of performance invalidity (i.e., failure on 4 of 15 PVTs, and 4 of 12 PVTs, respectively), the data from these cases provided compelling evidence that the patients were not performing to true ability, but only in specific cognitive domains. These illustrations raise concerns regarding the simple "summing" of abnormal PVT scores, and instead argue for tabulation of the number of PVT failures within each cognitive domain. As with interpretation of standard neurocognitive measures, "false-positive" PVT findings would be more likely those reflecting isolated failures "scattered" across the various domains. In addition, the second case illustrates that PVT failures are not necessarily comparable in "weight," in that extreme failures provide strong evidence of noncredible performance regardless of the number failed.

PROTECTING CREDIBLE POPULATIONS AT RISK FOR PVT FAILURE

The flurry of publications addressing the important issue of interpretation of data from multiple PVTs reveals an emerging consensus that multiple PVT failures are unusual in most clinical populations. However, there are two patient groups for whom this is not true: patients with dementia and patients with low intelligence. For example, Dean et al. (2009) observed that in a dementia sample with no motive to feign, patients with Mini-Mental State Examination (MMSE) scores of 15–20 failed an average of 47% of PVTs administered, and in patients with MMSE scores of ≤15, 83% of PVT cut-offs were exceeded. In a separate publication, Dean et al. (2008) showed that in a sample with no motive to feign, patients with IQ scores from 70 to 79 failed 17% of administered PVTs, while patients with IQs from 60 to 69 failed 44% of PVTs. Keary et al. (2013) observed that PVT scores declined as IQ decreased, but association with IQ disappeared as IQ rose. As discussed above, Larrabee (2014b) asserted that some additional patient groups may fail PVTs at a high rate (e.g., stroke with aphasia, moderate to severe traumatic brain injury with brain imaging abnormalities and prolonged coma, severe psychiatric disturbance), but the likely moderator is low IQ and/or dementia. For example, psychotic patients who fail PVTs are those who meet criteria for dementia (MMSE scores ≤24; Back et al. 1996).

The best solution for the problem of PVT cut-off high false-positive rates in individuals with low IQ is to remove these subjects from primary validation samples, and to examine them separately, developing cut-offs that are tailored for the determination of actual versus feigned intellectual disability. We tested this method in a recent publication (Smith et al. 2014) which included 55 credible patients (no motive to feign) with IQ ≤75 ($n = 55$) and noncredible patients ($n = 74$) assumed to be feigning low IQ (IQ scores ≤75). The credible group scored better than the noncredible group on virtually all domains (attention, visual perceptual/spatial tasks, processing speed, verbal learning/list learning, and visual memory). With cut-offs set to maintain approximately 90% specificity in the credible group, sensitivity rates in identifying noncredible subjects were highest for verbal and visual memory and select attentional scores. When failure rates were tabulated across seven most sensitive scores (>40% sensitivity), two or more failures were associated with 85.4% specificity and 85.7% sensitivity, and three or more failures resulted in 95.1% specificity and 66% sensitivity. Thus, failure on three of the seven cut-offs was unusual in truly low IQ individuals, but use of these cut-offs still identified two-thirds of noncredible subjects who were feigning global cognitive dysfunction.

These results are promising and suggest a viable approach to protecting groups at risk for PVT failure despite performing to true ability: First, adjust individual PVT cut-offs to achieve approximately 90% specificity in the target credible group, and then tabulate the number of failures; increasing numbers of failures will be most likely due to symptom misrepresentation. The following case illustrates use of this technique.

DIFFERENTIAL DIAGNOSIS OF ACTUAL VERSUS FEIGNED LOW IQ

Case vignette

This 24-year-old patient sustained massive injuries when he ran in front of a car in an apparent suicide attempt during an acute psychotic episode. In the hospital emergency department the patient was noted to be awake and moaning with eyes open; Glasgow Coma Scale (GCS) was rated at 10. Neurologic exam was grossly nonfocal with movement in all extremities. The patient was found to have sustained multiple facial fractures and a fracture at the base of the skull, as well as several orthopedic fractures. Brain computed tomography (CT) did not show intracranial lesions but did reveal a small amount of blood in the posterior horns of the lateral ventricles. During his hospitalization the patient was described as making "steady improvement" and that he "recovered his mental status." Six weeks after injury he was transferred to a subacute facility for ongoing physical therapy and occupational therapy; discharge diagnoses included paranoid schizophrenia and cerebral concussion.

The patient had never lived independently from his family. At the age of 14 months he was observed to have episodes of briefly "passing out," and the differential diagnosis included absence seizures. He performed very poorly in school, began receiving special education services in the fourth grade, and did not begin reading until fifth or sixth grade. He reportedly had difficulty playing sports because "he didn't understand the rules." He had never held employment, obtained a driver's license, or been in a romantic relationship, and he was described as socially isolated throughout his schooling. His first documented psychotic episode began approximately 4 months prior to the injury. He was psychiatrically hospitalized, during which time he was described as confused and disoriented, responding to internal stimuli, selectively mute, and aggressive toward staff and patients, and with numerous bizarre behaviors (holding his ears while screaming, taking off his clothes, banging his head and punching himself, displaying waxy flexibility and posturing, and urinating and defecating on himself). With treatment his acute symptoms resolved, and he was released to home; however, shortly afterward his psychotic symptoms returned at which time the suicide attempt occurred.

The patient underwent neuropsychological evaluation at request of defense counsel three and a half years after the injury. On exam the patient presented as "young" and immature. He did not appear to be acutely psychotic; however, on one task he stopped responding and appeared possibly to either have had an absence seizure or to be reacting to internal stimuli. Responses were slowed. Thought processes were grossly within normal limits, but the patient displayed a knowledge deficit (e.g., for aspects of his medical history, symptoms, and treatment) which appeared to be

related primarily to low intelligence. Further, he counted on his fingers when solving math problems.

Neuropsychological scores for this patient are reproduced in Table 72.1, including performances on PVTs.

The patient failed PVTs from 9 of 14 separate tests using published cut-offs, which normally would suggest that he was not performing to true ability. However, overall IQ score was low (FSIQ = 75), and judged accurate (rather than as reflecting negative response bias) because it was consistent with very poor premorbid academic function. As shown in Table 72.2, when cut-offs adjusted for low IQ were employed for seven tests found to be most sensitive in the differential of actual versus feigned low IQ per Smith et al. (2014), the patient passed all measures.

A neuropsychological evaluation in a forensic context involves two main steps: (1) determination as to whether obtained scores reflect valid and accurate data, and if this criterion is passed, (2) ascertainment of the nature, extent, and cause of any neurocognitive compromise. If concerns regarding test score veracity are encountered on step 1, the examiner cannot move on to step 2. In the patient's case, it was concluded that he was most likely performing to his true ability level and that the remaining standard neurocognitive scores were usable. Those latter scores were interpreted as showing substantial impairments in processing speed and visual memory; impaired to average skills in visual perceptual/spatial skills, verbal memory, and executive functions; borderline to low average academic skills (word reading, spelling, math); and low average vocabulary range and basic attention.

Rey Word total correct (cut-off ≤7)	= 9 (passed)
Warrington total score (cut-off ≤38)	= 49 (passed)

The patient was considered not likely to have any current cognitive sequelae related to the injury three and a half years earlier. The available data suggested that the patient most

likely met criteria for a mild traumatic brain injury at that time. Records from his hospitalization referred only to a "cerebral concussion," and brain imaging was essentially normal. It is unclear whether the patient was rendered unconscious; in the emergency department he was described as awake and moaning with eyes open, and was trying to sit up. He had GCS of 10, which normally would fall within the moderate traumatic brain injury category, although it is unclear whether the patient's extensive orthopedic injuries contaminated the ratings. Further, he was described as "confused/disoriented" (score of 4 on verbal response section of the Glasgow Coma Scale), but this was also likely true prior to the suicide attempt due to his severe psychosis. Anterograde amnesia could not be reliably assessed due to sedation after the injury.

Reviews of the literature on neuropsychological function in mild traumatic brain injury (see Carroll et al. 2004, 120 studies; Dikmen et al. 2009, 33 studies), including six meta-analyses involving dozens of studies and thousands of patients in the aggregate (133 studies, $n = 1463$, Belanger et al. 2005; 21 studies, $n = 790$, Belanger and Vanderploeg 2005; 8 studies, Binder et al. 1997; 17 studies, $n = 634$, Frencham et al. 2005; 25 studies, $n = 2828$, Rohling et al. 2011; 39 studies, $n = 1716$, Schretlen and Shapiro 2003) show that patients who experience mild brain trauma have returned to baseline by weeks to months post-injury.

It was concluded that the patient had a long-standing, developmental intellectual disability as well as a psychotic disorder that were unchanged by the suicide attempt and related injuries three and a half years prior to exam, and that the patient had no current cognitive or psychiatric conditions stemming from that event. Of note, at the time of testing the patient was more functional than prior to the suicide attempt; for example, the patient's sister reported that he was now responding verbally to the family member's questions, whereas prior to the injury he did not.

SUMMARY

A critical goal within clinical neuropsychology is to quickly develop methods that assess for performance validity while adequately protecting credible patient subgroups who are at risk for being inaccurately determined to be malingering or otherwise not performing to true ability. One such method for protecting patients with low IQ is described in this chapter. Memory (especially recognition) and attentional PVT measures were found in the Smith et al. (2014) study to be most robust to low intelligence, and these are likely to show the most promise in differentiating actual versus feigned low IQ. Further, qualitative aspects of some memory recognition tasks may reveal error types that are not found in individuals with low IQ and would therefore be specific to noncredible performance; for example, Marshall and Happe (2007) indicated that it was rare for subjects with low IQ to produce "dyslexic" false-positive errors on the Rey 15-item recognition trial. Likewise, significantly below chance performance on forced choice measures would not be explainable on the basis of low IQ. Novel techniques may be worth pursuing, such as developing measures that assess for a "yes" response bias (exhibited by individuals with low IQ, but not necessarily adopted by noncredible individuals attempting to feign low IQ), such as on the Logical Memory recognition trial (Marshall and Happe 2007).

SUMMARY KEY POINTS

- Neuropsychologists have an obligation to carefully and comprehensively assess for performance validity during forensic neuropsychological exams through use of validated performance validity tests (PVTs).
- Performance validity is not a unitary construct, i.e., test takers may elect to underperform at differing timepoints during the exam and on differing types of neurocognitive tasks—there is no one noncredible profile.
- Adequate assessment of performance validity requires use of multiple PVTs interspersed throughout the neuropsychological exam to check for performance validity in "real time."
- Use of multiple PVTs does not result in substantially increased risk of false-positive identifications, except in the context of very low intelligence and dementia.
- Individuals with true low intelligence can be protected from inaccurate identification as noncredible through (1) setting PVT cut-offs to maintain less than 10% false-positive rates in low IQ populations, and (2) requiring multiple failures using these adjusted cut-offs.

Neuroimaging and forensic psychiatry

ROBERT A. SCHUG AND LEIDY S. PARTIDA

INTRODUCTION

Practitioners in forensic psychiatry stand to gain tremendously from an empirical understanding of the initiation, maintenance, and potential desistance from criminality. Neurobiological crime research (i.e., neurocriminology) has contributed extensively to criminological study for over 100 years (i.e., Lombroso 1876) and has offered a unique understanding of the etiological mechanisms underlying antisocial behavior. Neuroimaging (the application of technologies and techniques that generate visual representations of brain structure and functioning in living persons), one of the branches of neurocriminology (and the forensic neurosciences), has been an effective methodology in identifying structural and functional deficits in frontal, temporal, and subcortical regions in antisocial children and adults—findings that are largely supported by neurological studies of brain trauma in antisocial populations, and congruent with neuropsychological investigations revealing verbal, spatial, and executive dysfunction in antisocial adults and children. Findings from neuroimaging research have recently begun to impact criminal justice systems in various arenas, including applications in lie detection and judicial processes; and may enhance forensic psychological assessment and inform policies and procedures regarding the identification, management, and treatment of various types of individuals in forensic psychiatric settings.

Two crucial bases of knowledge are of value in informing the forensic clinical practitioner regarding neuroimaging applications to forensic psychiatric work: (1) an understanding of brain imaging studies to date, examining relationships between brain structure and function and various forms of psychiatric symptomatology (including thoughts, affects, and behaviors that may lead to clinically significant impairment); and (2) an understanding of how brain imaging evidence has been applied to criminal legal proceedings in the past (including the reasons why it may or may not have helped the defendant—which often relate to standards of admissibility of evidence). This chapter serves as an integrative review of findings in both of these areas. It provides a summary of key areas of neuroimaging research on criminal, violent, and antisocial behavior, as well as an overview of previous criminal cases in which neuroimaging evidence was incorporated into the adjudication process. Although the scope of forensic work may include both criminal and civil proceedings, the focus of this chapter is on the application of neuroimaging to criminal cases. As such, it first covers the growing body of work on brain imaging studies of criminal, violent, and antisocial behaviors, as well as the history of criminal cases in which an attempt was made (whether successful or not) to utilize brain imaging evidence in order to aid criminal defendants.

LEGAL ISSUES RELATED TO NEUROIMAGING

The practitioner in forensic psychiatry stands to benefit from an understanding of both the clinical and legal applications of neuroimaging. Recent years have shown a heightened emergence of neuroimaging techniques in the contemporary court system. Defense attorneys have introduced the lion's share of neuroimaging evidence, and judges to date have admitted the use of brain imaging techniques such as computerized axial tomography (CAT or CT), positron emission tomography (PET), single-photon emission computed tomography (SPECT), electroencephalography (EEG), and magnetic resonance imaging (MRI). The admittance of these types of scans has occurred in different phases of the trial. Although most research suggests neuroimaging evidence is typically introduced in the sentencing (or penalty) phase of a trial, it has also been introduced in the guilt and post-trial phases. Despite the interest and growing body of research on this topic, debates and criticisms indicate further research and testing are necessary. Some critics have indicated the use of brain scans during penalty phases of death penalty cases can be productive. One reason is that federal and state laws label mental impairment as a form of mitigating evidence, which can be considered by

a jury when deciding on capital punishment as a penalty. Another reason is that judges prefer to err in admitting the evidence, rather than negating it, in cases in which it could have reversed a death penalty sentence. Others believe neuroscience techniques to be too novel for appropriate use in courtrooms in criminal cases. Research findings suggest a bias in favor of the defense, commonly resulting in a verdict of not guilty by reason of insanity (Batts 2009, 261). Additionally, the novelty of neuroimaging techniques is associated with several key risks. For example, interpretations of neuroimaging scans may produce *false positives*—indications of brain abnormalities when the brain is actually normal, or *false negatives*—failure to elucidate abnormalities when the brain is in fact not normal (Moriarty 2008, 29). Researchers generally believe neuroimaging techniques are more efficient when utilized to mitigate charges. However, many have expressed the opinion that neuroimaging should not be introduced in a capital defense setting. Others have opined that neuroimaging techniques should be used to support other evidence of brain dysfunction (e.g., from a comprehensive social history investigation, neuropsychological testing, and evaluation by a neuropsychiatrist or neurologist), not utilized as the sole predictor of whether or not a defendant is guilty of a crime (Blume and Paavola 2011, 909; Moriarty 2008, 29).

Various legal issues have been identified in the literature related to neuroimaging. In criminal cases, neuroimaging evidence may have applications in insanity defenses (e.g., *People v. Weinstein*, 1992), as an indicator of criminal intent, in detecting deception by witnesses or defendants, and during the sentencing phases of trials in which the appropriateness of the death penalty must be determined (Yang et al. 2008, 65). Others have suggested its usefulness in predicting recidivism and future dangerousness, explaining the effects of trauma and mental illness, and predicting whether a person has a general propensity for violence (Blume and Paavola 2011, 909). Its (questionable) role as evidence of a defendant's past mental state has even been noted (Brown and Murphy 2010, 1119). For criminal proceedings, applications might include (1) demonstrating that a criminal defendant's brain is vulnerable to violence or aggression, based on similarities to the brains of other individuals characterized by violence or aggression in research studies; (2) diminished culpability—demonstrating that a criminal defendant lacked the behavioral controls to prevent him or her from acting in a criminal/violent manner, based on structural or functional deficits in brain regions associated with impulse control, response inhibition (prefrontal cortex), or aggression and violence (limbic system—see below); and (3) demonstrating that a criminal defendant's brain is marked by characteristics consistent with others with criminogenic mental illnesses such as psychopathy. Other legal issues related to neuroimaging data center on its admissibility for evidentiary purposes in court.

LEGAL CRITERIA FOR ADMISSIBILITY OF NEUROIMAGING EVIDENCE

For the forensic psychiatrist utilizing neuroimaging data, an understanding of the standards for its admissibility in court is paramount. Similar to other forms of evidence, neuroimaging data are subject to specific criteria in order to be admitted for evidentiary purposes in legal proceedings. According to Moriarty (2008), the state and federal court systems in the United States are required to abide by certain admissibility standards, though these standards are different. For example, the federal system utilizes the Federal Rules of Evidence (FRE) when deciding whether evidence should be admitted. Specifically, the U.S. Supreme Court identifies three court cases as precedents in the admission of expert evidence: *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, *General Electric Co. v. Joiner*, and *Kumho Tire Co., Ltd. v. Carmichael*. The states also abide by evidentiary rules, which mostly follow the FRE template; however, each state has different variations of it. These variations usually follow Rule 401 (evidence must be relevant), Rule 702 (which regulates admission of expert testimony), and Rule 403 (which modulates confusion and unfair prejudice).

The *Frye* general acceptance standard originated from a 1923 D.C. Court of Appeals decision, which stated that use of the polygraph for evidentiary purposes was relatively novel. Therefore, its high rate of unreliability and inconsistency prevented it from attaining scientific general acceptance and validity. This case served as the precedent for subsequent cases attempting to introduce novel scientific evidence in the court system, requiring courts to determine whether the given novel evidence has reached general admissibility or not. Currently, some states continue to follow the *Frye* general acceptance standard. The federal courts ceased using the *Frye* standard because of the belief it was incompatible with FRE. The *Daubert* standard arose when the U.S. Supreme Court subsequently heard the scientific case of *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, and held that all scientific evidence should be tested for the minimal standard of evidentiary reliability. This minimal standard of evidentiary reliability was determined by referring to the scientific method. Specifically, the court required that (1) the scientific theory or technique can be or has been tested, (2) the theory or technique has been subjected to peer review and publication, (3) there is knowledge of the potential or known rate of error of the theory or technique when applied, (4) the standards controlling the technique's operation exist and are maintained, and (5) the technique or theory has been generally accepted in the relevant scientific community. The subsequent cases of *General Electric Co. v. Joiner,* and *Kumho Tire Co., Ltd. v. Carmichael* also helped shape the general admissibility standard. In *Joiner*, the court ruled that methodology and conclusions are not entirely different from one another. Instead, a court could hold too much of an analytical gap exists between the data and expert opinion. In *Kumho Tire*, the court held that all expert

evidence (not just scientific) should follow the *Daubert* requirements (Moriarty 2008, 29).

Several key weaknesses in the legal treatment of neuroimaging evidence have been identified in the empirical literature—including those related to its admissibility. For example, some authors (e.g., Feigenson 2006, 233 and Moriarty 2008, 29) have noted the inconsistencies among states regarding the standards of admissibility of neuroimaging evidence to prove specific kinds of facts. Although the federal courts are required to follow the Supreme Court's reliability standard, the states are not. While most states follow *Frye* or *Daubert* standards, there are variations from state to state in the applications of these standards (with some states even having their own unique standards). Overall, states following the *Frye* standard place emphasis on reliability, whereas those utilizing *Daubert* emphasize determining the acceptance and reliability of the evidence. Feigenson (2006, 233) also noted that the admissibility and persuasiveness of neuroimaging evidence (i.e., PET and SPECT in particular) depend greatly on the case-specific context.

Finally, it has been observed that on more than two-fifths of the instances in which neuroimaging evidence (i.e., PET and SPECT specifically) has been an issue in court, its proponents have presented or sought to present it to judges alone (e.g., before administrative law judges or relating to non-jury issues, such as competency to stand trial or injunctive relief), not juries. This is significant in that concerns about the courtroom use of fMRI data are often focused on their use by jurors, yet more often than not judges (not jurors) will be the decision makers on issues related to the offering of neuroimaging evidence. In fact, a high rate of admissibility for PET and SPECT evidence (82% as of 2006) has been noted, due possibly to the large proportion of bench proceedings where juries are not present and do not need to be protected from insufficiently reliable evidence (Feigenson 2006, 233). Egan (2007, 62) notes that the *Daubert* rule makes the trial judge responsible for the initial determination of relevance and reliability of evidence, and the trial judge must have a reasonable understanding of the science itself in order to do so. Given the technically complex information associated with neuroimaging, this can be a heavy burden. Ultimately, the admissibility of neuroimaging evidence in court as a whole remains to date nuanced and contextually variable, and it is critical for the practitioner in forensic psychiatry to understand the limitations of neuroimaging's potential evidentiary value in the eyes of the court.

DATA RELEVANT TO THE LEGAL CRITERIA

The steadily increasing body of scientific literature related to neuroimaging and criminal, violent, and antisocial behavior is directly relevant to the legal criteria for admissibility outlined by the Daubert standard—speaking to its testability, peer review and publication, potential/known error rate, operational standards, and acceptance by the scientific community. Neuroimaging data also have significant utility in informing the forensic psychiatric opinion. Given the growing number of studies in this area, along with the level of technical expertise needed to interpret and synthesize results, an organized understanding of the current and recent studies of neuroimaging and antisocial behavior can be challenging for the forensic psychiatric practitioner. One useful organizational framework for understanding this material is via the classification of studies by anatomical regions of the brain, as specific brain structures and areas have consistently demonstrated relationships with various forms of antisocial behavior. Previous empirical investigations have targeted specific regions of interest (ROIs) including whole-brain or right and/or left hemispheres, different areas of the cerebral cortex (e.g., frontal and temporal lobes), subregions within these lobes (e.g., the prefrontal cortex of the frontal lobe—which itself may be sectioned into subvolumes including the orbitofrontal cortex [OFC], and dorsolateral prefrontal cortex [DLPFC]), and specific subcortical structures such as the hippocampus and amygdala of the limbic system (discussed elsewhere—see Glenn and Raine 2014, 54; Raine et al. 2005, 185; and Yang et al. 2010, 9). Traditionally, these studies have examined gray matter (composed predominantly of neuronal cell bodies) and/or white matter (consisting chiefly of myelinated axon tracts, and representing connectivity between various brain areas).

A second useful organizational approach for the forensic practitioner is classifying previous research according to the imaging technique used. Neuroimaging studies of antisocial behavior may be structural or functional in nature. Structural technologies focus on the length, thickness, shape, volume, density and other physical properties of a particular brain area or component, using tools such as computed tomography (CT) scanning, diffusion tensor imaging, and structural magnetic resonance imaging (sMRI). Functional approaches examine the amount of neural activity present in any given brain region, utilizing tools such as positron emission tomography (PET), single photon emission computed tomography (SPECT), and functional magnetic resonance imaging (fMRI). Finally, a third useful organizational approach is organizing research according to the type of antisocial population examined. Participants recruited for neuroimaging studies of antisociality may be classified by specific crime type (e.g., murderers) or antisocial characteristics/behaviors (e.g., violence, aggression, gambling, or substance use). Participants may also be characterized by psychiatric disorders demonstrating associations with antisocial attributes (e.g., conduct disorder, oppositional defiant disorder, substance abuse disorders, bipolar disorder, schizophrenia, antisocial personality disorder, and psychopathy).

Most neuroimaging studies of antisocial behavior are undertaken with the overarching goal of making precise structural or functional measurements of ROIs in

individuals characterized by crime, antisociality, or violence, and comparing these measurements to those of individuals without these characteristics (i.e., normal, healthy controls). Any identified between-groups differences in these measurements may be considered as potential brain-based neurobiological correlates of the various forms of antisocial behaviors and traits of study. What follows is a review of current, recent, and foundational neuroimaging research on antisocial behavior, using the aforementioned organizational frameworks (i.e., investigations of frontal and temporal lobes, the structural and functional findings from studies of these brain areas, and—to some degree—findings from studies of various antisocial populations).

FRONTAL LOBE AND PREFRONTAL CORTEX

The frontal lobe region constitutes roughly one-third of the cerebrum—far and away the largest quantity of cortical volume in humans compared with other animal species. Nearly two centuries of scientific inquiry have identified associations between frontal lobe damage and behavioral control problems, and investigations from the more-recent past have suggested the frontal lobe's role in the perception and appraisal of emotional stimuli, and the regulation of emotion responses (Schug et al. 2009, 326). In recent decades, neuroimaging studies have continued to suggest that deficits in structural and functional aspects of the frontal lobe play a critical role in the neurobiological processes underlying antisociality and violence. Earlier imaging studies of antisocial individuals often reported on more macro-level analyses of brain structure and functioning—understandable, given the spatial resolution limitations of the imaging techniques available at that time (although whole-brain volume analyses have been conducted in more-recent studies, e.g., Barkataki et al. 2006, 239). Nonetheless, these studies often implicated the frontal lobe in associations with various forms of offending. For example, an earlier meta-analysis of 20 structural and functional imaging studies found frontal lobe deficits to be associated with violent offending and temporal lobe deficits with sexual offending, and violent sexual offending to be associated with dysfunction in both lobes (Mills and Raine 1994, 145). Findings from diffusion tensor imaging research have also indicated frontal lobe white matter structural defects associated with violence (e.g., Hoptman et al. 2005, 133; Li et al. 2005, 184). Additionally, several PET studies have reported significantly reduced glucose metabolism in the frontal cortex, particularly the anterior medial frontal region and left white frontal matter, in individuals characterized by violent behavior (e.g., Goyer et al. 1994, 21; Raine et al. 1997, 495; Soderstrom et al. 2000, 29).

Several subregions comprise the surface of the frontal lobes, which have distinctive patterns of connectivity with other areas of the cerebral cortex, along with structures deep below the brain's surface. A number of these cortical subregions are believed to be involved in *executive functioning*, an umbrella term referring to the cognitive processes facilitating future, goal-oriented behavior (Morgan and Lilienfeld 2000, 113), including abilities such as maintaining an appropriate problem-solving set for future goal attainment (Luria 1966). Executive functioning is broadly composed of four distinct cognitive domains: volition (i.e., capacity for intentional behavior), planning (i.e., identification and organization of the steps and elements needed to carry out an intention or achieve a goal), purposive action (i.e., translation of an intention or plan into productive, self-serving activity), and effective performance (i.e., self-monitoring and self-correction; Lezak et al. 2004). Each of these domains is required for socially and contextually appropriate behavior and successful self-serving conduct (Spreen and Strauss 1998; Lezak et al. 2004), which intuitively make executive functioning and associated brain regions promising areas for studying the etiology of crime, violence, and antisociality.

The prefrontal cortex (i.e., the prefrontal region of the frontal lobe) eventually became a primary region of investigation for earlier neuroimaging research on antisocial behavior. In terms of structural findings, Raine and colleagues (2000, 119), using sMRI, found reductions in prefrontal gray volumes in individuals with antisocial personality disorder (ASPD) (who were significantly more violent) compared to controls and individuals with substance dependence. In fact, individuals in the ASPD group were characterized by 11% less prefrontal gray matter volume compared to controls, and nearly 14% less prefrontal gray matter volume compared to those in the substance dependent group. However, white matter volume in the prefrontal area did not differ significantly across the three groups. More recently, reduced prefrontal volumes were identified in violent schizophrenia patients compared to controls, and increased scores on an impulsivity measure were associated with reduced prefrontal volumes (Kumari et al. 2009, 39).

Raine et al. (1997, 495) conducted one of the classic functional imaging studies in this area, examining 41 murderers pleading not guilty by reason of insanity, and 41 age- and sex-matched controls. For this study, PET imaging was used during a continuous performance challenge task. Results indicated murderers demonstrated reduced glucose metabolism in lateral and medial prefrontal cortical regions (i.e., left and right medial superior frontal cortex, left anterior medial cortex, and right OFC). In a subsequent study (Raine et al. 2008), these authors found murderers characterized by affective (i.e., reactive and emotionally based) aggression demonstrated reduced lateral and medial prefrontal functioning when compared to controls, whereas those characterized by predatory (i.e., purposeful and goal driven) aggression had reduced medial prefrontal but not lateral prefrontal functioning relative to the control group. Another study (Volkow et al. 1995, 243) also found reduced glucose metabolism bilaterally in prefrontal regions in violent psychiatric patients with intermittent explosive disorder (IED; an illness defined by repeated unplanned outbursts of aggression which are disproportionately intense relative to situational factors and result in harm to

property and person) compared to healthy controls. Finally, a meta-analysis of 43 structural and functional neuroimaging studies (Yang and Raine 2009) reported significantly reduced structure and function in prefrontal regions in antisocial individuals.

Dorsolateral prefrontal cortex

Researchers have come to recognize the prefrontal cortex as a composite of anatomically distinct subsystems, rather than a unitary structure (Dinn and Harris 2000, 173), and differentiations have been made between the functional properties of the orbitofrontal/ventromedial and dorsolateral prefrontal sectors (Damasio 1994; Lapierre et al. 1995, 139). These subvolumes may have critical yet differential associations with the emotional and behavioral components of antisocial behavior and violence. For example, multiple sources of evidence suggest that the dorsolateral prefrontal cortex (DLPFC) mediates executive functions (Dinn and Harris 2000, 173) and is involved with the temporal integration of behavior (Lapierre et al. 1995, 139). The DLPFC also plays a critical role in inhibitory control, which is necessary for the development of moral conduct and moral cognition (Kochanska et al. 1997, 1).

Structural deficits in the DLPFC have been identified in antisocial boys with substance dependence (Dalwani et al. 2011, 295); they have also been associated with emotional deficits in psychopathic individuals (Zamboni et al. 2008; Yang et al. 2009, 736), and aggressive symptoms of conduct disorder (Fairchild et al. 2013, 86). Functional deficits in the DLPFC have been identified in antisocial substance-dependent boys (Crowley et al. 2010) and have also been associated with behavioral inhibition and impulsivity in individuals with ASPD (Völlum et al. 2010, 123), impaired decision-making ability in young offenders (Syngelaki et al. 2009, 1213), and alcoholism in ASPD patients with a history of violent behavior (Laasko et al. 2002). van Holst et al. (2012) found that gamblers showed increased DLPFC and ACC in response to gambling-related cues compared to controls. Other researchers failed to identify functional deficits in psychopaths when performing DLPFC tasks (Basoglu 2008, 72; Blair et al. 2006, 153; Roussy and Toupin 2000, 413). Interestingly, an fMRI study of community individuals (Glenn et al. 2009, 909) found increased psychopathy scores to be related to increased activity in the right DLPFC during an emotional moral decision-making task.

Orbitofrontal cortex

The orbitofrontal cortex (OFC; also known as the ventromedial prefrontal cortex) is critical in guiding behavior by processing the reward–punishment value of stimuli, and thus plays a key role in controlling violent acts (Damasio et al. 1994). The OFC, however, modulates sensitivity to reinforcement contingencies (see Dinn and Harris 2000, 173 for a review), and is involved with inhibiting inadequately motivated actions and modulating aggressive behavior and autonomic reactivity (see Lapierre et al. 1995, 139 for a review). In humans, this system contributes more to social and self-awareness than the DLPFC (Damasio 1994; see also Lapierre et al. 1995, 139 for a review). Pathologies of the OFC/VMPFC appear similar to psychopathy, whereas clinical DLPFC syndromes appear somewhat incompatible (Lapierre et al. 1995, 139).

Structural deficits in the OFC have been identified in violent males diagnosed with ASPD and type 2 alcoholism (Laasko et al. 2002), violent offenders with substance abuse disorders (Schiffer et al. 2011, 1039), men with ASPD (Raine et al. 2011, 227), aggressive and impulsive psychiatric inpatients (Antonucci et al. 2006, 213), and boys diagnosed with conduct disorder (CD) (Huebner et al. 2008, 540); and have been associated with gender differences (i.e., girls more so than boys) in children characterized by aggression and behavioral problems (Boes et al. 2008, 677). Additionally, gray matter volumetric increases in the OFC have been associated with increases in callous–unemotional traits in girls with CD (Fairchild et al. 2013, 86). Functional deficits in the OFC have been reported in violent individuals relative to nonviolent controls (e.g., Mathews et al. 2005, 287; Kumari et al. 2006, 159; Joyal et al. 2007, 97); in boys with antisocial behavioral and substance abuse problems (Crowley et al., 2010); in adolescents with behavioral problems (White et al. 2013, 315); in children with CD, oppositional defiant disorder (ODD), and psychopathic traits (Finger et al. 2011, 152), and individuals with borderline personality disorder or ASPD (Völlum et al. 2004, 39); and have been associated with increased lifestyle and antisocial psychopathic traits in violent patients with schizophrenia (Dolan and Fullam 2009, 570). Structural and functional studies have also identified abnormalities in the connectivity between the OFC and amygdala in psychopathic individuals and adolescents with CD (Marsh et al. 2011, 279; Passamonti et al. 2012).

TEMPORAL LOBE

The temporal lobe is associated with several different brain functions: namely, memory retention and storage, organization of sensory input, language production, visual perception, and emotional responses. The temporal lobe has been a popular region of interest in neuroimaging studies of antisocial behavior, which have foundations in the classic investigations of murderers using electroencephalography (EEG) that noted functional abnormalities in this region (Stafford-Clark and Taylor 1949; Hill and Pond 1952, 23; Mundy-Castle 1953, 103). Both structural and functional neuroimaging investigations have identified temporal lobe deficits that have been related to various forms of antisocial, aggressive, and violent behavior (Dolan 2010, 199).

Structural deficits, including various forms of volume reductions, have been identified in the temporal lobe regions of antisocial individuals. For example, Dolan and colleagues (2002, 105) found 20% reductions in volume in frontal and temporal lobes in impulsive–aggressive men with ASPD compared to controls. Similar studies examining reduced

gray matter have found consistent results in individuals diagnosed with ASPD, CD, and psychopathy (Kruesi et al. 2004; Pridmore et al. 2005, 856; Muller et al. 2008; Gregory et al. 2012). Barkataki and colleagues (2006, 239) used structural MRI to compare volumes of numerous brain structures among 13 men with ASPD, 13 men with schizophrenia and a history of violence, 15 nonviolent men with schizophrenia, and 15 healthy nonviolent male controls. Results indicated ASPD men were characterized by reduced whole brain and temporal lobe volume, as well as increased putamen volume, relative to controls. Using a cortical thinning approach, Yang and colleagues (2009) found that cortical gray matter in the right frontal and temporal cortices was significantly thinner in psychopaths compared to nonpsychopathic controls. Finally, using sMRI, Huebner et al. (2008, 540) identified reduced bilateral (i.e., on both sides of the brain) temporal lobe volumes in a sample of 23 boys diagnosed with CD compared to age- and IQ-matched controls.

Several literature reviews of functional imaging studies have consistently indicated aggressive and violent individuals tend to be characterized by functional deficits in the temporal lobe (Bufkin and Luttrel 2005, 176). In terms of PET findings, Volkow and colleagues (1995, 243) found reduced rates of glucose metabolism in medial temporal regions in eight violent psychiatric patients relative to eight normal comparison subjects, while Raine and colleagues (1996) found an abnormal asymmetry in glucose metabolism in the medial temporal lobe (reduced activity in the left hemisphere compared to the right) in murderers compared to controls. Wong and colleagues (1997, 49) also found that patients with schizophrenia who committed single or minor offenses demonstrated reduced activity in anterior temporal lobe structures compared to normal controls. Furthermore, Soderstrom and colleagues (2000, 29) examined several ROIs in an sMRI and SPECT study of 21 impulsive violent offenders referred for pretrial forensic evaluations and 11 healthy controls. Although results indicated no structural deficits among violent offenders, reduced regional blood flow in the right medial temporal and right angular gyri was noted in the violent offender group when compared to controls. Another study (Goethals et al. 2005, 187) found that patients with either borderline personality disorder or ASPD demonstrated reduced rCBF in both right temporal and prefrontal regions compared to controls, but that those characterized by violence also showed structural deficits. Finally, an earlier fMRI investigation (Kiehl et al. 2001, 677) reported criminal psychopaths were characterized by overactivation in the bilateral fronto-temporal cortex when processing emotional stimuli. In sum, consistent evidence from structural and functional neuroimaging studies continues to implicate the temporal lobe in various forms of criminality, violence, and antisocial behavior.

To summarize, the growing number of neuroimaging investigations to date speaks to the "state of the science" of neuroimaging and its application to forensic psychiatric practice, and may be relatable—in the eyes of the court—to its testability, peer review and publication, potential/known error rate, operational standards, and acceptance by the scientific community. As such, this body of empirical work is useful to those in the criminal justice system tasked with determining the evidentiary value of neuroimaging, particularly as it may measure up to admissibility standards such as *Daubert*.

REASONING PROCESS: PREVIOUS FORENSIC APPLICATIONS OF NEUROIMAGING EVIDENCE

The reasoning process leading to the forensic psychiatry opinion may be best understood by examining previous criminal cases in which neuroimaging evidence was introduced and accepted in order to inform the opinion of the court. The exact number of these cases, however, is somewhat difficult to ascertain. For example, in 2006, Feigenson noted there were approximately 130 court cases involving PET and/or SPECT evidence, and only two involving fMRI evidence (Feigenson 2006, 233; Yang et al. 2008, 65). Subsequently, Farahany (2012) noted the number of cases in which judges acknowledged neuroscience evidence (though not necessarily *neuroimaging* evidence specifically) in their opinion increased from 112 in 2007 to more than 1500 in 2011. Farahany also noted a significant limitation to these figures: the actual number of cases in which neuroscience evidence is presented is likely much higher because trial data are notoriously incomplete. A sizable number of criminal cases are settled outside of court, and Westlaw (the database utilized in this particular research) does not contain every criminal case (Farahany 2012).

Table 73.1 lists 27 such cases, in chronological order, separated according to whether the criminal defendant was aided by the evidence or not, or (in two cases) when subsequent evidence was identified which would have aided the defendant if admitted. While it serves as a qualitative review of sorts, it is not a comprehensive or exhaustive list of such cases, as the present cases were culled from the empirical literature and reflect only those garnering the attention of scholars in forensic neuroscience. As such they do not constitute a representative "sample," but rather a sample of convenience. Nonetheless, many of these cases were noteworthy in some way and offer an opportunity to discern some initial patterns regarding the use of brain imaging evidence in the courtroom.

First, of the 25 cases reported in the empirical literature in which neuroimaging evidence was admitted, it can be noted that there are more than double the number of cases in which neuroimaging evidence did not actually aid the defendant ($n = 17$ or 68%) compared to those in which it did ($n = 8$ or 32%). Second, these cases appear to be more commonly from California ($n = 6$ of 25 or 24% of the total), particularly so in the cases in which the defendant was aided ($n = 3$ of 8 or 37.5%). Cases from New York were the second-most common among all of the cases ($n = 4$ of 25 or 16% of the total), and the most common among cases in which the defendant was not aided ($n = 3$ of 17 or 17.6%). Third, among these cases it appears that

Table 73.1 Criminal cases involving neuroimaging evidence

Cases in which evidence was accepted and aided defendant							
Case	**Year**	**Location**	**Case type**	**Imaging technique**	**Imaging outcome**	**Legal outcome**	**Source**
U.S. v. Hinckley	1982	Washington, DC	Capital case (attempted assassination of President Ronald Regan): Guilt phase	CAT	Showed widened sulci (associated with schizophrenia)	Not guilty under reason of insanity	Moriarty (2008)
McNamara v. Borg	1991	California (9th Circuit)	Capital case: Guilt phase	PET	Introduced in support of the defendant's mitigation claim that he was suffering from schizophrenia.	Defendant sentenced to life imprisonment rather than execution. Jurors later acknowledged they were significantly influenced by the neuroimaging evidence in their decision to spare the defendant's life.	Moriarty (2008), Snead (2006)
Hoskins v. State	1999	Florida	Capital case: Sentencing phase	PET	Results indicated abnormality (unspecified)	Florida Supreme Court reversed imposition of death penalty, and remanded case for a new penalty proceeding so defendant could present a PET scan showing a brain abnormality (failure to allow neuroimaging evidence at the sentencing phase of trial was held to be reversible error).	Moriarty (2008), Snead (2006)
U.S. v. Aramony	2001	New York	53 charges (embezzlement, misappropriation of funds): Guilt phase	MRI	MRI scan used to argue a shrinking brain defense: showed widened sulci (associated with schizophrenia)	Shortly after brain imaging evidence determined admissible, entered into plea bargain that resulted in substantially reduced 7-year prison sentence.	Batts (2009), Snead (2006)

Table 73.1 (*Continued*) Criminal cases involving neuroimaging evidence

Cases in which evidence was accepted and aided defendant							
Case	**Year**	**Location**	**Case type**	**Imaging technique**	**Imaging outcome**	**Legal outcome**	**Source**
State v. Marshall	2001	Washington	Capital case: Sentencing phase	MRI, EEG, SPECT	Court noted that MRI, EEG, and SPECT evidence indicated defendant's brain had severe atrophy, electric brain activity far slower than that of a normal person, and abnormal blood flow.	Death penalty sentence reversed	Moriarty (2008)
People v. Williams	2004	California	Sentencing phase	PET	Defendant's expert testified that the PET scan showed decreased activity in the frontal lobe, basal ganglia, and thalamus, and stated that this pattern is often visible with traumatic brain injuries or psychotic disorders, and was associated with impaired judgment and an inability to regulate aggression.	Jury convicted defendant on a lesser charge of second-degree murder, rather than first-degree murder.	Moriarty (2008)
Peter J. Chiesa	2004	California	Capital case: Sentencing phase	SPECT	Introduced to show that the murder was not calculated, but rather the result of a poorly functioning brain	Evidence admitted at trial along with expert testimony and the jury found for two counts of second-degree murder.	Snead (2006)
Commonwealth v. Pirela; *Commonwealth v. Morales*	2004	Philadelphia	Capital case (two separate death sentencing proceedings for Simon Pirela [aka, Simon Morales]): Sentencing phase	MRI, PET	In first case, introduced to support mitigating factors of diminished capacity, brain damage, and mental impairment; in subsequent case, introduced to show mental retardation	Admitted in each case; in both cases, based on neuroimaging evidence, death sentences vacated and life imprisonment imposed	Snead (2006)

(*Continued*)

Table 73.1 (*Continued*) Criminal cases involving neuroimaging evidence

Cases in which evidence was accepted but did not aid defendant							
Case	**Year**	**Location**	**Case type**	**Imaging technique**	**Imaging outcome**	**Legal outcome**	**Source**
People v. Herbert Weinstein	1992	New York	Charged with second-degree murder (accused of strangling his wife and throwing her body from their 12th-story Manhattan apartment to make her death appear as a suicide): Sentencing phase	PET	Large cyst located in the membranous casing of the brain (the arachnoid membrane) had increased the pressure on defendant's frontal cortex, creating metabolic imbalances in the region.	Judge ruled that jury could hear defendant had a brain cyst, but not that such cysts or abnormal brain metabolism increase violent tendencies. Defendant pled guilty to the reduced charge of manslaughter.	Batts (2009)
People v. Holt	1997	California	Capital case: Sentencing phase	PET, EEG	PET scan images and an EEG showing abnormalities in both temporal lobes and damage to the cingulate gyrus region of the brain, which experts testified was consistent with aberrant sexual behavior	Evidence admitted, but the jury was not persuaded by this mitigation evidence and sentenced the defendant to death.	Snead (2006)
United States v. Gigante	1997	New York	Racketeering, RICO, conspiracy to murder, an extortion conspiracy, and a labor payoff conspiracy: Sentencing phase	PET	According to defense expert's interpretation, defendant was suffering from organic brain dysfunction, possibly due to Alzheimer disease or multi-infarct dementia.	The court held the PET scan evidence was unreliable, and furthermore neither credible nor persuasive. They also found his abnormalities could be a result of drug use.	Moriarty (2008)
Robinson v. State	1999	Florida	Capital case: Sentencing phase	SPECT	Petitioner had suffered brain damage to his frontal lobe (given little weight because of insufficient evidence that brain damage caused petitioner's conduct)	Trial court did not abuse discretion in denying the motion for the evidence in this case where petitioner did not show need for the additional test.	Snead (2006)

Cases in which evidence was accepted but did not aid defendant							
Case	**Year**	**Location**	**Case type**	**Imaging technique**	**Imaging outcome**	**Legal outcome**	**Source**
People v. Kraft	2000	California	Capital case: Sentencing phase	PET	Experts testified images were consistent with obsessive-compulsive disorder.	Evidence admitted, but the jury was unmoved by this evidence and sentenced defendant to death.	Snead (2006)
People v. Protsman	2001	California	First-degree murder: Sentencing phase	PET	Decrease in frontal lobe activity	The California Court of Appeal, following the general acceptance standard as mandated by their state supreme court, upheld the trial court's decision that the proposed use of the PET scan (as opposed to the PET scan itself) testimony did not meet the general acceptance standard. Sentenced to life in prison without the possibility of parole, plus one year for the weapon enhancement.	Moriarty (2008)
Rogers v. State	2001	Florida	Capital case: Sentencing phase	PET, MRI	MRI scan revealed no impairment.	Expert testimony did not posit that a PET scan would be essential in this particular case and that any impairment was sufficiently demonstrated with evidence already admitted.	Snead (2006)

(*Continued*)

Table 73.1 (*Continued*) Criminal cases involving neuroimaging evidence

Cases in which evidence was accepted but did not aid defendant							
Case	**Year**	**Location**	**Case type**	**Imaging technique**	**Imaging outcome**	**Legal outcome**	**Source**
United States v. Mezvinksky	2002	Pennsylvania	Defendant charged with federal fraud crimes and attempted to raise a mental health defense, alleging bipolar disorder, frontal lobe organic brain damage, and Lariam-induced toxic encephalopathy: Guilt phase	PET	Abnormal scan with frontal lobe decrease consistent with Alzheimer disease, toxic encephalopathy, or Pick disease.	PET scan was permitted in court. Neuroimaging was not enough for which defendant offered such testimony.	Moriarty (2008)
Harrington v. State	2003	Iowa	Capital case: Sentencing phase	Computer-based brain testing measuring P300 wave patterns of brain activity (i.e., brain fingerprinting)	Petitioner's brain did not contain information about the murder, but evidence confirmed his brain contained information consistent with his alibi.	Court did not rule on the admissibility of this evidence because it found resolution of this issue unnecessary to resolution of the appeal. (Due process claim was dispositive.)	Snead (2006)
Ex Part Simpson	2004	Texas	Capital case: Sentencing phase	MRI, EEG	An MRI and an EEG were introduced in the sentencing phase at trial, but the court concluded that the expert testimony did not establish mental retardation for the defendant.	The imaging and expert testimony were admissible, but unpersuasive as to preventing death sentence.	Snead (2006)
People v. Goldstein	2004	New York	Murder in the second degree: Sentencing phase	PET	Reduction in metabolism in the frontal lobe and the basal ganglia	Neuroimaging was not enough to convince the jury.	Moriarty (2008)

Table 73.1 (*Continued*) Criminal cases involving neuroimaging evidence

Cases in which evidence was accepted but did not aid defendant							
Case	**Year**	**Location**	**Case type**	**Imaging technique**	**Imaging outcome**	**Legal outcome**	**Source**
Roper v. Simmons	2005	Missouri	Capital case: Sentencing phase	Research based on anatomical brain scans, including fMRI	Neuroimaging showing that the adolescent brain was insufficiently developed to support functions such as long-term planning, impulse control, risk assessment, etc.	Finding that juveniles are more prone to violent behavior and to peer pressure, the court cited the amicus briefs relying on the neurological evidence.	Snead (2006)
Slaughter v. State	2005	Oklahoma	Capital case: Sentencing phase	Brain fingerprinting based on MERMER effect	Introduced as new evidence supporting innocence. When asked salient details of the crime scene, petitioner's brain response to that information indicated "information absent," indicating he did not have knowledge of "salient features of the crime scene."	Court found insufficient evidence to support a conclusion that brain fingerprinting would meet Daubert evidence standard.	Snead (2006)
Smith v. Anderson	2005	Sixth Circuit	Capital case: Sentencing phase	CAT, MRI	Evidence offered did not actually prove an organic brain disorder.	Court found evidence introduced not compelling enough to sustain the motion	Snead (2006)
State v. Reid	2006	Tennessee	Capital case: Penalty phase	PET	PET scan admitted as evidence, indicating shrinkage or atrophy of the left temporal lobe of the defendant's brain, that the damage had likely been caused by a head injury when the defendant was 7 or 8 years old, and that such injury was associated with psychotic disorders producing delusional states.	Tennessee Supreme Court noted without critique that trial court admitted PET scan evidence during penalty phase of a capital murder. Defendant was nonetheless found competent to stand trial.	Moriarty (2008)

Cases in which evidence was accepted but did not aid defendant							
Case	**Year**	**Location**	**Case type**	**Imaging technique**	**Imaging outcome**	**Legal outcome**	**Source**
State v. Mercer	2009	South Carolina	Capital case: Charged with armed robbery and shooting: Penalty phase	SPECT	SPECT scan showed questionable abnormality which did not prove dementia, poor judgment, etc.	Defendant sentenced to death	Blume and Paavola (2011)
United States v. Semrau	2012	Tennessee	Charged with three counts of health-care fraud: Penalty phase	fMRI (lie detection)	Two scans indicated he was telling the truth; one indicated he was lying.	Judge decided it would not be admitted as a defense; Defendant found guilty.	Shen and Jones (2011)
Cases in which evidence was obtained post-verdict, which could have aided defendant							
Case	**Year**	**Location**	**Case type**	**Imaging technique**	**Imaging outcome**	**Legal outcome**	**Source**
State v. South	1993	South Carolina	Capital case: Prior to trial	CAT	CAT scan was admitted, but was read as normal.	Convicted of murder and sentenced to death for a drive-by shooting of a police officer. Six years later, and MRI revealed a brain tumor that the radiologist had previously failed to discover.	Blume and Paavola (2011)
Zachary Short v. South Carolina	2005	South Carolina	Murder: Post conviction	MRI, PET	MRI and PET scans revealed significant abnormalities in defendant's brain structure and function. He also demonstrated poor performance on tests of verbal and abstract reasoning, impulsivity, and tactual memory-functions—largely associated with prefrontal and central cortex areas of the brain.	Tried and convicted for murdering police officer in Aiken, South Carolina.	Blume and Paavola (2011)

neuroimaging evidence was predominantly introduced during the sentencing phase of the criminal proceedings. For cases in which the evidence did not aid the defendant, this discrepancy is much more pronounced (i.e., $n = 16$ of 17 or 94.1% of cases) relative to cases in which neuroimaging evidence aided the defendant (i.e., $n = 5$ of 8 or 62.5% of cases).

Regarding imaging techniques, PET evidence was used most often in these cases ($n = 13$ of 25 or 52%), followed by MRI ($n = 8$ of 25 or 32%). For cases in which the defendant was aided, PET was used in four cases (50%), as the sole technique in three cases (75% of the cases it was used), and in conjunction with MRI in one case. On balance, MRI was utilized in three cases (37.5%), as the sole technique in one case and in conjunction with other methods in two cases (including the aforementioned case with PET). For cases in which the defendant was not aided, PET was used in nine cases (52.9%), as the sole technique in seven cases (77.8% of the cases it was used), and in conjunction with MRI in one case. On balance, MRI was utilized in five cases (29.4%), as the sole technique in one case and in conjunction with other methods in four cases (including the aforementioned case with PET). This may reflect the relatively high rates of admissibility of PET and SPECT (related to their use more so in proceedings before judges rather than juries) discussed by Feigenson (2008, 233—see above), or perhaps a reflection of technological advances in neuroimaging procedures, with the courts' willingness—over the time frame indicated—to admit evidence from a more established "tried and true" method such as PET (an older neuroimaging method) rather than a more-recent, less-proven technology (such as MRI). In fact, the long-standing conflict the law has between innovative science and reliability has been noted in the literature (Egan 2007, 62). In summary, while PET appears to have been the most prevailing technique among these cases, the proportion of cases using PET and MRI appears largely similar across cases in which the defendant was and was not aided by neuroimaging evidence. As such, the neuroimaging technique per se may not have played a substantive role in the effectiveness of the assistance to the defendant in each case.

Regarding neuroimaging outcome and how imaging data were applied (e.g., informing the forensic psychiatric opinion), eight of the cases (32% of overall cases) reported imaging findings to be associated with actual psychiatric or medical disorders (i.e. schizophrenia, psychotic disorders, Alzheimer disease, dementia, obsessive–compulsive disorder, toxic encephalopathy or Pick disease). Schizophrenia was the disorder most commonly referred to in the cases that aided the defendant ($n = 3$ or 37.5%), and this disorder was not mentioned in the cases in which the defendant was not aided. On balance, Alzheimer disease was the condition most-often mentioned in cases in which the defendant was not aided ($n = 2$ or 11.8%), and this disease was not mentioned in cases in which the defendant was aided. Only eight cases (32% of overall cases) mentioned structural or functional deficits in specific brain regions empirically associated with crime, violence, or antisociality (i.e., related to findings from the studies reviewed above); these cases were overwhelmingly among those in which the defendant was not aided (i.e., $n = 7$ of 8 or 87.5%).

It is noteworthy that while a modest number of cases, Table 73.1 listed psychiatric or medical disorders in their applications of neuroimaging evidence, none appear to have spoken to the putative relationships between these specific disorders and crime, violence, or antisocial behavior (see Schug and Fradella 2015)—in other words, *why* these disorders would have played a role in the defendants' criminal acts. Now, it is clear that the potential value of neuroimaging data in informing the diagnostic process—particularly for the forensic psychiatrist—cannot be overstated. The diagnostic capabilities of current neuroimaging techniques must be closely scrutinized, but it stands to reason that the effectiveness of these techniques in diagnosing various psychiatric and medical disorders will increase as more advanced technologies become available. Several recent studies have demonstrated the utility of various neuroimaging methods in diagnosing neuropsychiatric disorders such as ADHD, schizophrenia, Tourette syndrome, obsessive–compulsive disorder, major depression, bipolar disorder, borderline personality disorder, and Alzheimer disease (Tebartz van Elst et al. 2003, 163; Pearlson and Calhoun 2007, 158; Borairi and Dougherty 2011, 155; Bansal et al. 2012, 1; Klöppel et al. 2012, 457). In terms of the reasoning process, it is important for the forensic psychiatric practitioner, however, to go beyond utilizing neuroimaging techniques merely for diagnostic purposes, and instead be able to conceptualize the forensic client diagnostically and legally in terms of how these disorders or their symptoms may specifically contribute to criminal, violent, and antisocial behavior.

SUMMARY

Ongoing neuroimaging research has contributed to a greater empirical understanding of the initiation, maintenance, and potential desistance from criminal behavior; and this body of research can be of significant value to the field of forensic psychiatry. Organizational frameworks for this research related to brain regions of study, neuroimaging methods, and types of antisocial populations can be of tremendous benefit to the forensic psychiatry practitioner; as well as an appreciation for legal issues related to neuroimaging, criteria for its admissibility in court, and how existing data contribute to its evidentiary value. It must be remembered that neuroimaging as a practice is still in its infancy, and applications to psychiatry in general and forensic psychiatry in particular (i.e., in areas of the criminal justice system such

as criminal proceedings) must be made with caution. The forensic psychiatrist should note that neuroimaging research and forensic psychiatric applications are inextricably bound, with each serving both to inform and benefit from the other. It is hoped that this interdependence of research and practice will contribute to a growing base of evidence from which the causes and cures of criminality will eventually be revealed.

SUMMARY KEY POINTS

- The forensic psychiatric practitioner may most effectively understand neuroimaging evidence to date using organizational frameworks related to anatomical regions of the brain, imaging technique used, or type of antisocial population studied.
- Structural and functional neuroimaging studies of criminal, violent, and antisocial persons to date have largely focused on the frontal lobe and its subvolumes, the temporal lobe, and subcortical structures found within the limbic system.
- Brain imaging evidence is subject to Frye and Daubert standards in terms of admissibility to court, though these standards are not consistently applied in the United States from state to state or at the federal level.
- A review of criminal cases reported to date in the empirical literature indicates neuroimaging evidence is most often introduced during the sentencing phase, and more often consists of PET scan data. Criminal cases in which this evidence actually aided the defendant appear markedly less common.

Malingering

PHILLIP J. RESNICK

INTRODUCTION

Malingering is defined in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*) as "the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs" (American Psychiatric Association [APA] 2013, 726). In contrast, *factitious disorders* involve the intentional production of false symptoms in the absence of obvious external rewards. Both disorders require a deceitful state of mind. Feigning is the deliberate fabrication or gross exaggeration of symptoms without any assumptions about its goals.

Malingering can be categorized into (1) pure malingering, (2) partial malingering, and (3) false imputation. When an individual feigns a disorder that does not exist at all, this is referred to as *pure malingering*. When an individual has actual symptoms but consciously exaggerates them, it is called *partial malingering*. *False imputation* refers to the attribution of actual symptoms to a cause consciously recognized by the individual as having no relationship to the symptoms. For example, a claimant who is aware that he is suffering from posttraumatic stress disorder (PTSD) due to an earlier trauma may falsely ascribe the symptoms to a car accident in order to receive compensation.

Wooley and Rogers (2014) tested this model by assessing whether various types of malingerers were able to fake PTSD without being classified as feigning. The partial malingering group proved to be the best feigning group in achieving these two goals. Surprisingly, the partial malingering group was no more successful than the false imputation group in eluding detection. Although the false imputation feigners simply needed to attribute their current PTSD symptoms to a different trauma, they added additional symptoms and distress. They took a "more is better" approach.

Persons usually malinger mental illness for one of the following five purposes: First, criminals may seek to avoid punishment by pretending to be incompetent to stand trial, insane at the time of the crime, or worthy of mitigation at sentencing. Second, malingerers may seek to avoid conscription into the military or to avoid combat. Third, malingerers may seek financial gain from social security disability, veterans' benefits, workers' compensation, or damages for alleged psychological injury. Fourth, prisoners may malinger to obtain drugs, or to be transferred to a psychiatric unit in order to facilitate escape or do "easier time." Finally, malingerers may seek admission to a psychiatric hospital to obtain free room and board, known colloquially as "three hots and a cot."

CLINICAL METHODS FOR DETECTING MALINGERING

Clinicians should utilize multiple sources of data including interviews, collateral sources, and psychometric tests in detecting malingering (Resnick 2008; Zapf and Grisso 2012). Reliance on clinical interviews alone will not allow the examiner to diagnose malingering in any but the most obvious cases. When a litigant is suspected of malingering, the clinician must look carefully for evidence of inconsistency in symptoms:

1. There may be inconsistency in the subject's report itself. For example, a malingerer may articulately explain that he or she is confused and unable to think clearly.
2. There may be inconsistency in what a person reports and the symptoms that are observed. For example, a malingerer may state that he or she is hearing voices during the interview but shows no evidence of being distracted.
3. There may be inconsistency in observation of the symptoms themselves. For example, a hospitalized patient may behave in a befuddled manner with a psychiatrist, but then play excellent poker on the ward with other patients.
4. There may be inconsistency between performance on psychological testing and a malingerer's report of his or her level of performance. For example, a litigant may

state on an intelligence test that he or she does not know how many legs are on a dog, but be performing well as an investment banker.
5. There may be inconsistency between what the malingerer reports and how genuine symptoms manifest themselves. For example, a defendant may report visual hallucinations are seen in black and white, whereas genuine visions are seen in color.

APPROACHES TO DETECTING MALINGERING

Clinicians should be particularly careful to ask open-ended questions of suspected malingerers and let evaluees tell their complete story with few interruptions. Details can be clarified later with specific questions. Inquiries about hallucinations should be carefully phrased to avoid giving clues about the nature of true hallucinations. The examiner should try to ascertain whether the subject has ever had the opportunity to observe psychotic people (e.g., during prior employment or in a family member). Clinicians may feel irritation at being deceived, but any expression of irritation or incredulity is likely to make the malingerer more defensive.

Clinicians may modify their interview style when defendants are suspected of malingering psychosis. The interview may be prolonged because fatigue diminishes the malingerer's ability to maintain a counterfeit account (Anderson et al. 1959). Rapid firing of questions increases the likelihood of getting contradictory replies from malingerers, but it may also create confusion among intellectually disabled persons. The clinician may get additional clues by asking leading questions that emphasize a different illness than the malingerer is trying to portray. Questions about improbable symptoms may be asked to see if the malingerer will endorse them. Another device is to mention, within earshot of the suspected malingerer, some easily imitated symptom that is not present. The sudden appearance of the symptom suggests malingering.

Inpatient assessment should be considered in difficult cases of suspected malingering. Feigned psychotic symptoms are difficult to maintain 24 hours a day. After completing a detailed examination, clinicians may decide to confront an evaluee with their suspicions. The suspected malingerer should be given every opportunity to save face. Once malingering is denied, there is a risk that it will be harder to admit later. It is better to say, "You haven't told me the whole truth," than, "You have been lying to me" (Inbau and Reid 1967).

Detailed knowledge about actual psychiatric symptoms is the clinician's greatest asset in recognizing simulated illness. Therefore, the phenomenology of genuine hallucinations, delusions, and other syndromes will be reviewed in this chapter.

MALINGERED HALLUCINATIONS

Before distinguishing genuine from true hallucinations, the clinician needs to differentiate between psychotic and nonpsychotic hallucinations. About 10%–15% of the healthy population sometimes experience auditory hallucinations (Sommer et al. 2010). Nonpsychotic hallucinations usually have a childhood onset with a median age of 12, whereas psychotic hallucinations begin at a median age of 21. Nonpsychotic hallucinations are often attributed to family members, spirits of dead people, or guardian angels, rather than real people such as Secret Service, police or malevolent neighbors (Laroi et al. 2012). Nonpsychotic hallucinations contain very little negative content, whereas almost all schizophrenic patients report some negative content. Nonpsychotic voices do not cause distress or disturbance in the daily life of the individual (Laroi 2012).

Persons reporting hallucinations with any atypical features should be questioned in great detail about the nature of their symptoms. Both psychotic patients (Goodwin et al. 1971) and patients with schizophrenia (Mott et al. 1965; Small et al. 1966) show a 76% rate of hallucinations in at least one sensory modality. The reported incidence of auditory hallucinations in patients with schizophrenia is 66% (Mott et al. 1965; Small et al. 1966). Eighty-two percent of hallucinating patients describe hallucinations in more than one modality (McCarthy-Jones et al. 2014). The incidence of visual hallucinations in persons with psychosis is estimated at 24% (Mott et al. 1965) to 30% (Small et al. 1966). Hallucinations are usually (88%) associated with delusions (Lewinsohn 1970).

Auditory hallucinations

Goodwin et al. (1971) described the following characteristics of auditory hallucinations. Both male and female voices were heard by 75% of the patients in their study. About two-thirds of hallucinating subjects could identify the person speaking (Goodwin et al. 1971; Kent and Wahass 1996; Leudar et al. 1997; McCarthy-Jones et al. 2014). The content of hallucinations was accusatory in over one-third of the cases.

Auditory hallucinations usually consist of single words or phrases, especially early in the disease process (Nayani and David 1996; Leudar et al. 1997). Hallucinated voices tend to become more complex over time, from single words to entire sentences. The number of voices heard also increases (Leudar et al. 1997). The syntax of long-standing auditory hallucinations is usually in complete sentences, and mirrors the syntax typically used by the evaluee (Nayani and David, 1996). In affective disorders, the content of the hallucination is usually mood-congruent and related to delusional beliefs (Asaad 1990).

Schizophrenic hallucinations tend to consist of personal insults, abuse, and derogatory comments about the patient or the activities of others (Goodwin et al. 1971; Oulis et al. 1995; Leudar et al. 1997; Laroi et al. 2012). Nayani and David (1996) reported that the most commonly encountered hallucinations were simple terms of abuse. Female subjects described insults conventionally directed at women

suggesting promiscuity. Men described male insults such as those imputing homosexuality.

About one-third of persons with auditory hallucinations reported that voices asked them questions. Voices never sought information such as, "What time is it?" or "What is the weather like?" Instead they asked chastising questions, such as "Why are you smoking?" or "Why didn't you do your essay?" (Leudar et al. 1997).

Leudar et al. (1997) found that most patients in their study engaged in an internal dialogue with their hallucinations. Many were able to cope with chronic hallucinations by incorporating them into their daily life as a kind of internal advisor. Interestingly, sometimes their hallucinated voices would insist on certain actions after the patient refused to carry them out. The voices would rephrase their requests, speak louder, or curse the patient for being noncompliant. In contrast, malingerers are more likely to claim that they were compelled to obey commands without further consideration. Some malingerers describe voices in a stilted manner, such as "Go commit a sex offense." Other malingerers describe far-fetched commands, such as a robber who alleged that (malingered) voices kept screaming, "Stick up, stick up, stick up!"

Hallucinated voices are usually perceived as benign, benevolent, or malevolent. In a study by Chadwick and Birchwood (1994), patients commonly said that evil commands were evidence that the voice was bad, and kind protective words were evidence that the voice was good. Malevolent voices evoke negative emotions (anger, fear, depression, anxiety). Patients often respond by arguing, shouting, noncompliance, and avoidance of cues that trigger malevolent voices. Benevolent voices usually provoke positive emotions (amusement, reassurance, calm, happiness). Patients often respond by elective listening, willing compliance, and doing things to bring on their benevolent voices.

A common myth in detecting faked hallucinations is that if someone replies that they hear their voices in one ear or the other, they are faking. This myth is belied by the fact that when asked to place a finger on the part of the head that they could locate their voices, 71% of genuine hallucinators selected a place close to one ear (Hoffman et al. 2008). In persons with genuine auditory hallucinations, 71% were able to recall the first time they heard voices (Hoffman et al. 2008).

Persons suspected of feigning auditory hallucinations should be asked what they do to make the voices go away or diminish in intensity. Genuine patients are often able to stop auditory hallucinations when their schizophrenia is in remission, but not during the acute phase of their illness (Larkin 1979). Frequent coping strategies among persons with genuine schizophrenia are as follows: (1) specific activities (working or watching TV); (2) changes in posture (e.g., lying down or walking); (3) seeking out interpersonal contact; (4) taking medication; and (5) prayer (Falloon and Talbot 1981; Kanas and Barr 1984). Schizophrenic hallucinations tend to diminish when patients are involved in activities (Goodwin et al. 1971; McCarthy-Jones and Resnick 2014). Patients with genuine malevolent hallucinations usually develop some strategies to decrease them (McCarthy-Jones and Resnick 2014).

The suspected malingerer may be asked what makes the voices worse. Eighty percent of persons with genuine hallucinations reported that being alone worsened their hallucinations (Nayani and David 1996; McCarthy-Jones and Resnick 2014). Voices were also made worse by listening to the radio and watching television (Leudar et al. 1997). News programs were particularly hallucinogenic.

Atypical features were reported in less than 5% of patients with auditory hallucinations (McCarthy-Jones et al. 2014). Atypical voices included having a voice whose normal speaking tone is yelling, hearing only female voices, hearing only children's voices, and never hearing the same voice twice. Stephane et al. (2006) identified other atypical content of auditory hallucinations: "I hear voices of animals." "The voices sound robotic." "The voices refer to me as Mr. or Mrs." "I hear voices whenever I open a window."

Some malingerers may allege that their hallucinations went away after 1 or 2 days of treatment with antipsychotic medication. The first time a psychotic patient is given antipsychotics, the median length of time it takes for hallucinations to completely clear is 27 days (Gunduz-Bruce et al. 2005). In persons treated for schizophrenic hallucinations after 1 month, their voices became less loud and less distressing (Schneider et al. 2011). After 6 months of antipsychotics, they heard their voices less frequently and felt that they had more control of them. They also recognized they were self-generated (Schneider et al. 2011).

COMMAND AUDITORY HALLUCINATIONS

Command hallucinations are auditory hallucinations that instruct a person to act in a certain manner. Command hallucinations are easy to fabricate in order to support an insanity defense. The majority of commands to commit dangerous acts are not obeyed. Thus, the examiner must be alert to the possibility that a defendant may fake an exculpatory command hallucination or lie about an inability to refrain from a genuine hallucination. Knowledge of the frequency of command hallucinations and the factors associated with obeying commands are helpful in looking at the authenticity of such claims.

Hellerstein et al. (1987) found in a retrospective chart review that 38% of all patients with auditory hallucinations reported commands. Studies of schizophrenic auditory hallucinations found that 30%–67% included commands (Mott et al. 1965; Small et al. 1966; Goodwin et al. 1971; Hellerstein et al. 1987; McCarthy-Jones et al. 2014). Command hallucinations occurred in 30% (Goodwin et al. 1971) to 40% (Mott et al. 1965) of alcoholic withdrawal hallucinations. Patients with affective disorders reported that 46% of their hallucinations were commands (Goodwin et al. 1971).

Hellerstein et al. (1987) reported that the content of command hallucinations was 52% suicide, 5% homicide,

12% nonlethal injury of self or others, 14% nonviolent acts, and 17% unspecified. The research method of reviewing charts, rather than making direct inquiries, probably increased the relative proportion of violent commands since these are more likely to be charted.

Earlier research suggested that hallucinatory commands are generally ignored by patients (Goodwin et al. 1971; Hellerstein et al. 1987). McCarthy-Jones et al. (2014) found that 76% of their patients said they were able to resist their command hallucinations. However, Junginger (1990) reported that patients with hallucination-related delusions and hallucinatory voices that they could identify were more likely to comply with the commands. Kasper et al. (1996) reported that 84% of psychiatric inpatients with command hallucinations had obeyed them within the last 30 days. Among those reporting command hallucinations in a second forensic population, 74% indicated that they acted in response to some of their commands during the episode of illness (Thompson et al. 1992).

Junginger (1995) studied the relationship between command hallucinations and dangerousness. He found that 43% of the subjects reported full compliance with their most recent command hallucination. People are more likely to obey their command hallucinations if the voice is familiar, there are hallucination-related delusions (Junginger 1990), and the voice is perceived as powerful (Fox et al. 2004; Shawyer et al. 2008). Compliance with commands is less likely if the commands are dangerous (Junginger 1995; Kasper et al. 1996). A defendant alleging an isolated command hallucination in the absence of other psychotic symptoms should be viewed with suspicion. Noncommand auditory hallucinations (85%) and delusions (75%) are usually present with command hallucinations (Thompson et al. 1992).

Visual hallucinations

Persons with genuine visual hallucinations report that they are humanoid 70% of the time. A minority of visual hallucinations are animals or objects. Ninety-five percent of the time the visions are not something that the hallucinator has actually seen before. Over 80% of persons with visual hallucinations report that their response to their first visual hallucination was to be overwhelmed or fearful (Gauntlett-Gilbert and Kuipers 2003).

Visual hallucinations are usually of normal-sized people and are seen in color (Goodwin et al. 1971). Alcohol-induced hallucinations are more likely to contain animals (Goodwin et al. 1971). Visual hallucinations in psychotic disorders appear suddenly and typically without prodromata (Asaad and Shapiro 1986). Psychotic hallucinations do not usually change if the eyes are closed or open. In contrast, drug-induced hallucinations are more readily seen with the eyes closed or in darkened surroundings (Asaad and Shapiro 1986).

Occasionally, small (Lilliputian) people are seen in alcoholic, organic (Cohen et al. 1994), or toxic psychoses (Lewis 1961), especially anticholinergic drug toxicity (Asaad 1990; Contardi et al. 2007). The little people are sometimes 1 or 2 inches tall; at other times up to 4 feet in height. Lilliputian hallucinations are rarely seen in schizophrenia. Only 5% of visual hallucinations in the Goodwin study (1971) consisted of miniature or giant figures.

Visual hallucinations are volunteered much more often (46% versus 4%) by malingerers than by genuinely psychotic individuals (Cornell and Hawk 1989). Dramatic, atypical visual hallucinations should definitely arouse suspicions of malingering (Powell 1992).

MALINGERED DELUSIONS

Delusions are not merely false beliefs that cannot be changed by logic. A delusion is a false statement made in an inappropriate context and most importantly, with inappropriate justification. Normal people can give reasons, can engage in a dialogue, and can consider the possibilities of doubt. Persons with true delusions cannot provide adequate reasons for their beliefs.

Delusions vary in content, theme, degree of certainty, degree of systemization, and degree of relevance to the person's life in general. The more intelligent the person, the more elaborate his or her delusional system will usually be. According to Spitzer (1992), most delusions involve the following general themes: disease (somatic delusions), grandiosity, jealousy, love (erotomania), persecution, religion, being poisoned, and being possessed. Delusions of nihilism, poverty, sin, and guilt are commonly seen in depression. Technical delusions refer to the influence of such items as telephone, telepathy, and hypnosis. Delusions of technical content occur seven times more often in men than in women (Kraus 1994).

A malingerer may claim the sudden onset of a delusion. In reality, systematized delusions usually take several weeks to develop. As true delusions are given up, they first become somewhat less relevant to the everyday life of the patient, but the patient still adheres to the delusional belief. A decrease in preoccupation with delusions may be the first change seen with adequate treatment. In a later stage, the patient might admit to the possibility of error, but only as a possibility. Only much later will the patient concede that the ideas were, in fact, delusions (Sachs et al. 1974). The median length of time for delusions to fully clear after the first initiation of antipsychotic medication is 73 days (Gunduz-Bruce et al. 2005). Thus, malingering should be suspected if a person claims that a delusion suddenly appeared or disappeared.

In assessing the genuineness of delusions, the clinician should consider their content and the person's associated behavior. Malingerers' behavior usually does not conform to their alleged delusions, whereas acute schizophrenic behavior usually does. However, patients with schizophrenia may no longer behave in a manner consistent with their delusions after several months. Table 74.1 summarizes suspect hallucinations and suspect delusions.

Table 74.1 Suspect hallucinations and delusions

Auditory Hallucinations
Voices are unbearably distressing
Lack of strategies to diminish malevolent voices
Hearing voices of animals
Never hearing the same voice twice
Voice only yells
Voice sounds robotic
Hearing only children's voices
Hearing only female voices
Hallucinated questions seeking information
Allegation that all command hallucinations were obeyed
Hallucinations not associated with delusions
Stilted language reported in hallucinations
Visual hallucinations
Black and white rather than color
Dramatic, atypical visions
"Schizophrenic" hallucinations that change when the eyes are closed
Only visual hallucinations in "schizophrenia"
Miniature or giant figures
Visions unrelated to delusions or auditory hallucinations
Delusions
Abrupt onset or termination
Eagerness to call attention to delusions
Conduct not consistent with delusions
Bizarre content without disordered thinking

CLINICAL INDICATIONS OF MALINGERED PSYCHOSIS

All malingerers are actors who portray their psychoses as they understand them. Malingerers often overact their part. Malingerers sometimes mistakenly believe that the more bizarrely they behave, the more psychotic they will appear.

Malingerers are eager to call attention to their illnesses in contrast to schizophrenic patients, who are often reluctant to discuss their symptoms (Ritson and Forest 1970). One malingerer stated that he was an "insane lunatic" when he killed his parents at the behest of hallucinations that "told me to kill in my demented state." Malingering defendants may try to take control of the interview and behave in an intimidating manner. The clinician should avoid the temptation to terminate such an interview prematurely. Malingerers sometimes accuse clinicians of regarding them as faking. Such behavior is extremely rare in genuinely psychotic persons.

It is more difficult for malingerers to successfully imitate the form than the content of schizophrenic thinking (Sherman et al. 1975). Derailment, neologisms, and incoherent word salads are infrequently simulated. Positive symptoms of schizophrenia are faked more often than negative symptoms.

Malingerers give more approximate answers to questions than schizophrenic patients, such as "there are 53 weeks in the year" (Bash and Alpert 1980; Powell 1992). Persons malingering psychosis often fake intellectual deficits also (Bash and Alpert 1980; Schretlen 1988; Powell 1992). For example, a man who completed 1 year of college alleged he did not know the colors of the American flag. Malingerers are more likely to answer "I don't know" to detailed questions about psychotic symptoms, such as hallucinations. This response may simply mean that they do not know how to answer because they have never actually experienced the symptoms.

PSYCHOMETRIC TESTS FOR MALINGERING

The detection of malingering by standardized psychometric testing has been the focus of considerable research in recent years. The Structured Interview of Reported Symptoms (SIRS) was designed by Rogers et al. (1992) specifically to detect malingered psychiatric illness. The Minnesota Multiphasic Personality Inventory-2 (MMPI-2) is the most validated psychometric test for evaluating suspected malingering of psychopathology. Readers are referred to the Rogers (2008) book for details of detection of malingering with psychological testing, and to Chapter 71 of this book for psychological testing specific to evaluating malingered psychosis.

CLINICAL INDICATORS OF MALINGERED INSANITY DEFENSES

A crime without apparent motive, such as killing a stranger, lends credence to the presence of true mental disease. Genuine psychotic explanations for rape, robbery, or check forging are unusual. Another indicator of malingered psychosis is evidence from family members and collateral sources that the Global Assessment of Functioning (GAF) for the preceding year is inconsistent with the evaluee's current presentation (Kucharski et al. 1998).

In assessing defendants for criminal responsibility, clinicians must determine whether they report malingered symptoms at the time of the act, and/or malinger symptoms at the time of the examination. Some malingerers mistakenly believe that they must show ongoing symptoms of psychosis in order to succeed with an insanity defense. When defendants report psychiatric symptoms at the time of their examination, the clinician has the opportunity to see whether the alleged symptoms are consistent with genuine illness and current psychological testing results.

Defendants who have true schizophrenia may malinger an exculpatory symptom to escape criminal responsibility. These are the most difficult cases to accurately assess. Clinicians have a lower index of suspicion for malingering because of the history of psychiatric hospitalizations and the

presence of residual schizophrenic symptoms. These defendants are able to draw upon their prior experience with hallucinations and their observations of other psychotic people in hospitals. They know what questions to expect from clinicians. If they spend time in a forensic psychiatric hospital, they may learn how to modify their story to fit the exact criteria for an insanity defense. Clinicians should not think of malingering and psychosis from an "either/or" perspective (Rogers et al. 1994).

Several clues can assist clinicians in the detection of fraudulent not guilty by reason of insanity (NGRI) defenses (Table 74.2). A psychotic explanation for a crime should be questioned if the new offense fits the same pattern as the defendant's previous convictions. Malingering should be suspected in defendants pleading insanity if a partner was involved in the crime. In a study at the Michigan Center for Forensic Psychiatry, 98% of successful NGRI acquittees acted alone (Thompson et al. 1992). Most accomplices of normal intelligence will not participate in psychotically motivated crimes.

Malingering defendants are more likely to present themselves as blameless within their feigned illness (Resnick 2008). This conduct was demonstrated by a man who pled NGRI to a charge of stabbing an 11-year-old boy 60 times with an ice pick. He stated that he was sexually excited and intended to force homosexual acts on the victim, but abandoned his plan when the boy began to cry. When he started to leave, 10 faces in the bushes began chanting, "Kill him, kill him, kill him." He yelled, "No," and struck out at the faces with an icepick. The next thing he knew, "the victim was covered with blood." The autopsy showed a cluster of stab wounds in the victim's head and neck—which was inconsistent with the defendant's claim that he struck out randomly at multiple faces in the bushes. His version showed a double avoidance of responsibility: (l) the faces told him to kill, and (2) he claimed to have attacked the hallucinated faces, not the victim. In other words, if even half of his story was believed, he hoped to avoid criminal responsibility. After his conviction, he confessed to six unsolved sadistic homosexual murders.

Table 74.2 Clues to malingered insanity defenses

Malingering should be suspected if any of the following are present:

1. A nonpsychotic, alternative rational motive for the crime
2. Suspicious hallucinations or delusions (see Table 74.1)
3. Current crime fits an established pattern of prior criminal conduct
4. Absence of any active or subtle signs of psychosis during the evaluation
5. Presence of a partner in the crime
6. Double denial of responsibility (e.g., disavowal of the crime plus attributing the crime to psychosis)
7. Alleged intellectual deficit coupled with alleged psychosis
8. Alleged illness inconsistent with documented level of functioning

MALINGERING IN POSTTRAUMATIC SITUATIONS

The types of psychiatric disorders that most commonly occur after a traumatic experience are posttraumatic stress disorder (PTSD), depressive disorders, post-concussion syndromes, and, occasionally, psychoses. Plaintiffs' attorneys strongly favor the diagnosis of PTSD because the diagnosis itself includes evidence that the symptoms are due to the litigated event. In contrast, depression after a traumatic event could be attributed to multiple other causes.

Posttraumatic stress disorder

ASSESSMENT OF PTSD SYMPTOMS

The diagnosis of PTSD is based almost entirely on the claimant's self-report of subjective symptoms. Accessibility on the Internet of specific *DSM-5* criteria permit the resourceful malingerer to report the "right" symptoms. The assertion that individuals dream or think about a traumatic event should be verified by others who have heard them talk about it in situations that are not related to the litigation. In addition, the clinician must obtain a detailed history of living patterns preceding the stressor. For example, symptoms such as difficulty concentrating or insomnia may have been present before the traumatic event. The clinician must carefully examine the reasonableness of the relationship between the symptoms and the stressor, the time elapsed between the stressor and symptom development, and the relationship between any prior psychiatric symptoms and current impairment.

Clinicians who simply inquire about specific symptoms of PTSD and other diagnostic criteria in the *DSM-5* will be easily fooled. Lees-Haley and Dunn (1994) found that 97% of untrained college students were able to endorse symptoms of checklists to meet the diagnosis of major depression, while 86% were able to meet the criteria for PTSD.

The clinician should insist on detailed illustration of PTSD symptoms. Coached claimants may know which PTSD symptoms to report but may not be able to elaborate on them with convincing personal life details. Invented symptoms are more likely to have a vague or stilted quality (Pitman et al. 1996). The examiner should see if litigants minimize other causes of their symptoms or exaggerate the severity of the compensable accident. Clinicians should also look for actual evidence in the mental status exam of irritability, difficulty concentrating, and an exaggerated startle response.

CLUES TO MALINGERED PTSD

Malingerers may depict themselves and their prior functioning in exclusively complementary terms (Layden 1966). Persons with PTSD insomnia compared to others with insomnia are more likely to have fear of the dark, fear of

going to sleep, waking up with the covers torn apart, talking during sleep, waking up confused, and waking up from a frightening dream and then finding it hard to return to sleep (Inman et al. 1990).

Traumatic dreams occur in about 70% of persons with PTSD. About 50% of genuine nightmares in PTSD show variations on the theme of the traumatic event. For example, a woman who was raped may have dreams in which she feels helpless and is tortured without being raped. Posttraumatic nightmares, as contrasted with lifetime nightmares unrelated to trauma, are almost always accompanied by considerable body movement (van der Kolk et al. 1984). Body movement may be confirmed by the sleeping partner or disarray of sheets and covers. PTSD patients often awaken with the affect of the original trauma (Mellman et al. 1995).

Postconcussion syndromes

SYMPTOMS OF POSTCONCUSSION SYNDROME

Approximately 1.7 million traumatic brain injuries occur each year in the United States (APA 2013). Epidemiological studies indicate that a considerable number of minor head trauma patients report memory impairment, difficulty concentrating, a low threshold for fatigue, and abnormal levels of irritability (Wrightston and Gronwall 1980). Mild dysphoria, general psychological discomfort, and problems returning to previous employment were associated with this cognitive dysfunction. Neuropsychological assessment, with its focus on attention and concentration skills, visuomotor functioning, and memory abilities is particularly useful in the differential diagnosis of head injury and PTSD.

ASSESSMENT OF MALINGERED POSTCONCUSSIVE SYNDROME

Approximately 25%–50% of claimants of cognitive dysfunction are found to use suboptimal effort when given neuropsychological assessment (Guilmette et al. 1994; McAllister 1994; Youngjohn et al. 1995). The examiner must also not assume that symptoms reported after an accident are caused by the accident. It is common for symptoms reported by head-injured claimants to be present before their head injury. Table 74.3 shows the percentage of head-injured patients and control patients who alleged symptoms on a checklist.

Table 74.3 Frequency of symptoms reported after head injury

	Claimants (%)	Controls (%)
Anxiety or nervousness	93	54
Sleeping problems	92	52
Headaches	88	62
Back pain	80	48
Fatigue (mental or physical)	79	58
Dizziness	44	26

Source: Modified from Lees-Haley PR and JT Dunn. 1994. *Journal of Clinical Psychology* 50:252–256.

Considerable research has been done regarding faked memory loss. Although actual retrograde amnesia is characteristically brief in mild head injury, malingerers tend to overplay their memory loss. They may give implausible answers to questions regarding overlearned autobiographic data, such as their own name, age, gender, and social security number (Levin et al. 1992; Rogers and Correa 2008).

Several clues may be helpful in distinguishing faked from genuine ongoing memory problems. Brain injury does not impair procedural memory, such as driving a car or riding a bicycle. If memory is impaired for new learning, recollection of the head injury itself suggests faking. If a litigant volunteers several examples of memory failure, the degree of recollection itself suggests faking. Malingering is also suggested if the subject scores more poorly on questions labeled "memory testing" than on other questions that require similar memory. Another strategy to detect feigned cognitive impairment is the "floor effect." Some questions are so easy that an incorrect response is evidence of malingering. For example, the sum of two plus two or the number of legs on a dog are questions that even individuals with significant impairment can answer correctly (Rogers and Correa 2008).

Forced-choice tests are useful in assessing faked memory impairment. Forced-choice testing for memory is based on (1) presenting a large number of items in a two-choice format and (2) comparing the person's performance to the likelihood of success based on chance alone (i.e., no ability). The probability of purely guessing the correct response is 50%. The compelling conclusion is that the evaluee who scores below probability is deliberately motivated to perform poorly (Frederick et al. 1994; Soliman and Resnick 2010). Two of the more commonly used forced-choice memory tests are the Portland Digit Recognition Test (PDRT) and the Test of Malingered Memory (TOMM) (Bass and Halligan 2014).

MALINGERED AFFECTIVE DISORDERS

Depression may be malingered by defendants pursuing an insanity defense and by civil litigants seeking compensation. The Beck Depression Inventory (BDI) and the Hamilton Depression Rating Scale (HDRS) rely solely on self-report and thus are quite easy to malinger. Although malingerers of depression will claim depressed mood, they are less likely to report more subtle symptoms such as early morning awakening, diurnal variations in mood, psychomotor retardation, or loss of interest in sex. Malingerers may report difficulty falling asleep, while sleep disturbances in genuine depression more typically involve multiple awakenings, especially in the early morning hours.

In assessing whether a person is genuinely depressed, clinicians should look for a sad facial expression. Alleged weight loss should be verified in medical records. This is

one of the best ways to show whether an evaluee is giving false information. Severe depression is often characterized by slow movements, slow speech, and difficulty concentrating. Assessment of difficulty concentrating can be made by seeing how attentive the evaluee is during a lengthy interview and whether he or she can spell a five-letter word backward.

Clinicians should be concerned about malingering when persons seeking hospital admission make conditional threats (Lambert and Bonner 1996). Statements such as "If you don't admit me to the hospital, I will hurt myself or someone else" or "I will sue you if you don't admit me to the hospital" are more consistent with personality disorders than severe depression (Reccoppa 2009).

Malingering of mania is unusual. Litigants may claim a history of manic symptoms, but it is difficult to sustain the flight of ideas, pressured speech, grandiose mood, increased psychomotor activity, and decreased need for sleep seen in true mania. Inpatient evaluation of suspected malingerers will usually reveal that these symptoms are not sustained.

SUMMARY

The detection of malingered mental illness is sometimes quite difficult. The decision that an individual is malingering is made by assembling all of the clues from a thorough evaluation of a litigant's past and current functioning with corroboration from clinical records, psychological testing, and other people. Clinicians must be thoroughly grounded in the phenomenology of the mental disease being simulated. Although the identification of a malingerer may be viewed as a distasteful chore, it is critical in forensic assessments. Indeed, clinicians bear a heavy responsibility to assist society in differentiating true disease from malingered madness.

SUMMARY KEY POINTS

- Knowing the detailed phenomenology of genuine symptoms helps the clinician to identify faked symptoms.
- Nonpsychotic genuine hallucinations should not be mislabeled as faked hallucinations.
- Malingered hallucinations are often described as more intense than genuine hallucinations.
- Genuine delusions usually do not start or stop suddenly.
- Having genuine schizophrenia does not preclude faking an exculpatory hallucination.

Amnesia, hypnosis, and brainwashing

GIOVANA DE AMORIM LEVIN, JOHN BRADFORD, A.G. AHMED, AND SANJIV GULATI

INTRODUCTION

Research on memory has led to important advances on the characterization of amnesia in neurological conditions, such as traumatic brain injury, dementia, epilepsy, delirium, and other conditions. Other types of amnesia, such as dissociative amnesia, are less well understood. Dissociative amnesia and malingering are likely the most common presentation of amnesia in forensic psychiatric settings (Cima et al. 2002). The incidence of true amnesia in this type of setting is not clear in the scientific literature. Malingered amnesia is also seen frequently in forensic patients, and arguably is the most common manifestation of all types of malingering (Grondahl et al. 2009). Often, there is insufficient evidence to provide an expert opinion on the subject of malingered amnesia or the role of true amnesia. The true incidence of amnesia in specific forensic psychiatric clinical situations such as homicide and in other clinical situations seen in forensic psychiatry is insufficiently researched, which makes it difficult to provide an evidence-based expert opinion (Bourget and Whitehurst 2007). To complicate this further, it is very difficult to design studies and to apply tests to determine the presence of true amnesia, as well as to answer some of the complex forensic psychiatric issues related to claimed amnesia.

Research into the biological aspects of memory has shown its fundamental role in cognitive functioning. There are three recognized components to memory: registration of information (encoding), storage, and retrieval. Personality development and response to life events are based largely on experiences that are memorized. Associated emotions are also processed and combined in a dynamic fashion, resulting in integration of memory and learning.

BIOLOGICAL ASPECTS OF MEMORY

There have been extensive studies on memory and its mechanism, as well as the classification of types of memory. Memory (or amnesia) in the context of a forensic setting has been much less explored and remains an area of controversy (Bourget and Whitehurst 2007).

The most commonly accepted types of memory are short-term and long-term memory. Short-term memory holds a small amount of information to be used readily (working memory). Most of this information dissipates quickly, but a fraction of this information becomes part of long-term memory, usually by a conscious effort, repetition, or association with previously acquired knowledge. Long-term memory is further divided into declarative (episodic and semantic) memory and nondeclarative (procedural, such as skills and habits, priming and perceptual learning, simple classical conditional, and nonassociative learning) memory.

Brain areas associated with memory include the medial temporal lobe, hippocampus and related structures in the parahippocampal gyrus, amygdala, striatum, cerebellum, and the neocortex. The Papez circuit has been recognized as the key anatomical region for registration and storage of memory. The Papez circuit goes through the following pathway: hippocampal formation, fornix, mammillary bodies, mamillothalamic tract, anterior thalamic nucleus, cingulus, entorhinal cortex, and the circuit completes by connecting with the hippocampal formation (Papez 1934). The original concept of the Papez circuit (American Psychiatric Association [APA] 2000) in 1937, was later reconceptualized by Maclean in 1952 to include structures like the amygdala. He also coined the term the *limbic system*, earlier referred to by Broca as the limbic lobe (Newman and Harris 2009). The limbic system is involved in both memory and emotions. Review of the brain structures and biochemical pathways involved in memory is beyond the scope of this chapter, and the following segments will focus on amnesia, hypnosis, and brainwashing in clinical forensic practice (Squire and Kandel 2009; Squire and Dede 2015).

AMNESTIC DISORDER (NEUROCOGNITIVE DISORDER) AND DISSOCIATIVE AMNESIA

Amnesia is the term used to describe any loss or impairment of memory for facts, information, and experience. Amnesia results as a failure of some components of the memory process. In a simplified way, it can be classified as follows:

1. Failure of registration: For example, amnesia, secondary to delirium, epilepsy, intoxication, concussion
2. Failure of creating new memories: For example, Korsakoff dementia (alcohol-induced major neurocognitive disorder)
3. Failure to recall: For example, dissociative amnesia, malingered amnesia, dementias

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*) recognized delirium, dementia, amnestic disorder, and other cognitive disorders in a single group of disorders, for which an underlying pathological process and etiology could explain the cognitive deficit. Dissociative amnesia, a disorder of memory for which no underlying medical cause can be determined, was also recognized in *DSM-IV* under dissociative disorders (APA 2000). In the *DSM-IV*, amnestic disorder was defined as due to a general medical condition, substance-induced persisting amnestic disorder, and amnestic disorder not otherwise specified. In the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), the term *amnestic disorder* is no longer used and is now represented by the neurocognitive disorders (APA 2013). Under neurocognitive disorders, the *DSM-5* includes delirium, followed by syndromes of major neurocognitive disorders, mild neurocognitive disorder, and their etiological subtypes (such as Alzheimer, Huntington, Prion disease, and others), which include the dementias. Individuals with neurocognitive disorder have deficits primarily in cognitive functioning, and this is an acquired condition, rather than developmental. The cognitive functioning is a decline from previous level of performance in one or more cognitive domains, interferes (major neurocognitive disorder) or not (mild neurocognitive disorder) with independence in everyday activities, does not occur exclusively in the context of a delirium, and is not better explained by another mental disorder. The etiology is specified after the diagnostic criteria (APA 2013).

Psychogenic amnesia, initially described by Abeles and Schilder in 1935, was known as dissociative amnesia in the *DSM-IV*. Dissociative fugue was a separate diagnosis, also under dissociative disorders. In the *DSM-5*, dissociative amnesia continues to appear under dissociative disorders, with the difference that a dissociative fugue appears as a specifier (dissociative disorder with or without dissociative fugue). It is characterized by an inability to recall autobiographical information, usually of a traumatic or stressful nature, that is inconsistent with normal forgetfulness. Dissociative amnesia most often consists of localized or selective amnesia for a specific event or events, but it can manifest as generalized amnesia for identity and life history. The symptoms cause significant impairment in social, occupational, and other areas of functioning and are not attributable to the effects of a substance or a neurological or other medical condition. It is not better explained by dissociative identity disorder, posttraumatic stress disorder, acute stress disorder, somatic symptoms disorder, or major or mild neurocognitive disorder. It is a reversible memory impairment in which memories of personal experience cannot be retrieved in a verbal form (or, if temporarily retrieved cannot be wholly retained in consciousness).

AMNESIA IN THE FORENSIC PSYCHIATRIC SETTING

In the forensic psychiatric population, it is important to differentiate neurocognitive disorders, dissociative disorder, and malingering in the context of claims of amnesia. Medical history and laboratory and imaging studies are essential in determining possible organic causes of amnesia prior to considering dissociative amnesia and malingering (Rayel et al. 1999; Sommerlad et al. 2014).

As mentioned earlier in this chapter, it is estimated that there is a high prevalence of dissociative amnesia and malingering in forensic cases. The clinician should also be attentive to mixed amnesias, in which both a neurocognitive disorder and a dissociative amnesia or malingering coexist. For example, there's a strong association between violent crimes and states of acute intoxication. Acute intoxication may cause amnesia for the event, but in dissociative amnesia, it is the violent crime itself that is most likely to be associated with the dissociative amnesia as the individual dissociates from the traumatic event, usually the crime committed by the individual. The clinician should also strongly consider that the motivation for malingering amnesia is also the highest under the circumstances, as the individual hopes to escape criminal responsibility.

Amnesia claimed in the forensic psychiatric setting is usually retrograde, for the period of the alleged crime, but it can extend for minutes and even hours after the event, as described by Bradford and Smith in their study of amnesia in 30 cases of homicide (Bradford and Smith 1979). The prevalence of claimed amnesia for homicide and other violent offences varies between 20% and 70% in various studies, and it has been suggested that amnesia is more commonly claimed in serious charges (O'Connell 1960; Bradford and Smith 1979; Cima et al. 1984; Taylor and Kopelman 1984; Parwatikar et al. 1985; Schacter 1986). A study involving sexual offenders who claimed amnesia for the offense showed that these individuals had high degrees of violence and also fulfilled diagnostic criteria for potentially more harmful paraphilias (Bourget and Bradford 1995).

The mechanisms proposed to explain claims of amnesia for violent crimes in the absence of a neurocognitive disorder are summarized in Table 75.1.

The first proposed mechanism involves high levels of emotions, and it is not uncommon to have a spouse as the victim—that is, in cases of domestic homicide and domestic violence (Bradford and Smith 1979; Dalgleish and Cox 2002; Swihart et al. 1999). It has also been postulated that high levels of glucocorticoids may be responsible for impairment in retrieval in high stress situations. Glucocorticoid receptors have been found to mediate long-term memory formation (Joseph 1999; Chen et al. 2012; Osborne et al. 2015). With regard to the second proposed

Table 75.1 Common mechanisms of claims of amnesia in the forensic setting

Type of amnesia	References
Dissociative amnesia	Allen (1999), Holmes et al. (2005), Spitzer et al. (2006)
Substance-induced amnesia	Bradford and Smith (1979)
Malingered amnesia	Cima et al. (1984), Cima et al. (2002), Van Impelen et al. (2014)

mechanism, there are reports of height and frequency of alcohol abuse/intoxication in individuals claiming amnesia, for violent offences (Hopwood and Snell 1933; Lennox 1943; Bradford and Smith 1979). It appears that alcohol intoxication is only partially responsible for the claim of amnesia, because in some cases the alcohol level was shown to be too low to produce the clinical picture of amnesia. However, the effect of alcohol on the formation of memory is well established, and it is associated with high peak levels and chronicity of alcohol intake (Hopwood and Snell 1933; Lennox 1943; Bradford and Smith 1979; Goodwin 1995; Holmes et al. 2005). Recent evidence suggests that many of ethanol's effects on learning and memory stem from altered cellular activity in the hippocampus and related structures, and involve the NDMA receptor (Hicklin et al. 2011; White et al. 2000).

The third mechanism, malingering or malingered amnesia, is prevalent in the forensic population and is obviously expected to be even more prevalent when the motivation to avoid criminal responsibility is high, such as with serious violent crimes. Although in theory, these scenarios seem distinct, it is extremely difficult to clinically distinguish between the three mechanisms outlined above. It has been suggested that in addition to the clinical forensic interview, some tests may be helpful in diagnosing malingered amnesia, but it appears that the consensus among forensic psychiatrist is that establishing malingering in relation to amnesia is a difficult task (Cima et al. 1984; Cima et al. 2002; van Impelen et al. 2014).

Additional mechanisms/clinical presentations involving amnesia include the presence of schizophrenia, which although it does not fall into the categories of neurocognitive disorder or dissociative amnesia, can cause amnesia. Schizophrenia is often considered in criminal responsibility in forensic psychiatric settings. Further, amnesia in the context of sleep disorders, although less prevalent, may also have to be considered in criminal responsibility evaluations. Individuals suffering from schizophrenia have been reported to claim amnesia for serious crimes (Taylor and Kopelman 1984; Mafullul et al. 2001; Nolan et al. 2003). Nolan et al. (2003) suggest that confusion and disorganization as part of the psychosis may contribute to aggressive behavior in patients with schizophrenia, who also claim amnesia for the violent behavior (Nolan et al. 2003). Given the high prevalence of patients with schizophrenia in forensic psychiatric evaluations for criminal responsibility, clearly this is an area of research that warrants further attention in forensic mental health research.

Violent behavior has been described in sleep disorders, primarily in sleepwalking and sleep terrors (Bonkalo 1974). Ohayon and Schenck (2010) described violent behavior during sleep occurring in 1.6% of a large random stratified sample ($n = 19{,}961$) in an epidemiological study. Violent behavior during sleep was mostly found in individuals less than 35 years of age. In 72.8% of the cases of violent behavior during sleep, there was an association with parasomnias and sleep disorders (Ohayon and Schenck 2010). Sexual behavior during sleep has also been described and the term *sexsomnia* has been suggested for inclusion as a type of parasomnia (Shapiro et al. 2003). Several cases of sexsomnia associated with serious criminal charges have been reported (Ingravallo et al. 2014). An overview of sexsomnia and its medicolegal implications has been recently published by Organ and Fedoroff (2015).

A guide to evaluate amnesia in the forensic context has been proposed by Scott (2012). The recommendations are summarized in Table 75.2.

Table 75.2 Guide for evaluating amnesia in criminal behavior

Conduct a relevant medical and psychiatric examination	Include neurological examination and imaging when appropriate
Characterize the type of amnesia	Include type and extent of the memory deficit reported
Examine the possible role of substance use in the claimed amnesia	Special attention if the alcohol/drug level could produce amnesia
Evaluate degree of offense planning	Planning and premeditation should enhance an offender's memory of the event
Obtain collateral information	Medical, police reports and statements (offender and witnesses), alcohol/drug levels, jail records, others
Conduct appropriate psychological testing	SIRS, MMPI, Test of Memory malingering, Word memory test, SIMS, others, including symptoms validity testing
Potential psychophysiological tools	Guilt Knowledge Test (GKT), ERPs (evoke-related potential), others
Not recommended (due to vulnerability to suggestion)	Amytal interview, hypnosis

Source: Adapted from Scott CL. 2012. *Psychiatric Clinics of North America* 35(4):797–819.

HYPNOSIS AND THE AMYTAL INTERVIEW

The amytal interview was introduced in the 1930s as a treatment for patients suffering from psychosis and then subsequently used in nonpsychotic persons as a diagnostic tool in catatonia and hysterical states with muteness and stupor (Stoudemire 1982; Tollefson 1982). It was also used in abreaction to recover memory in dissociative amnesia and fugue states (Steinberg 2000). Amytal interviews are not recommended in the forensic psychiatric evaluation, as they may create distorted memories and/or implanted memories based on suggestion occurring during the procedure, which means that it is of very limited use in the forensic context (Kavirajan 1999). Sodium amytal also carries the risk of respiratory depression, and lorazepam has been suggested as a safe alternative in the treatment, and investigation of dissociative disorders, but for similar reasons, it would also be of very limited use in a forensic evaluation (Kavirajan 1999; Lee et al. 2011). Lynch and Bradford (1980) in a study to differentiate alcohol- or drug-induced amnesia from dissociative or malingered amnesia found that polygraphy was useful in making this differentiation. Although this was promising, no further research has been completed further evaluating this technique. Although this technique may be clinically relevant, the limitations on the use of polygraphy in a legal context would prevent its acceptance in court, according to decisions in *Frye v U.S.* (1923) and *Daubert v. Merrell Dow Pharmaceuticals Inc*. (1993). Similarly, hypnosis has been used to facilitate recall in clinical situations and also has been used by various police forces, but is not scientifically valid for use in court proceedings.

Hypnosis, which is based on suggestion, has also been rejected as a tool to recover memories in forensic psychiatric situations by the American Medical Association in 1985 (Council on Scientific Affairs 1985). The Council of Scientific Affairs found that recollections obtained during hypnosis can involve confabulations and pseudo-memories, and not only failed to be more accurate, but actually appeared to be less reliable than nonhypnotic recall. Further, the use of hypnosis with witnesses may have serious consequences for the legal process when testimony is based on material obtained from a witness under hypnosis for the purpose of refreshing recollection (Council on Scientific Affairs 1985). Recovered memories, with or without hypnosis or amytal have been controversial for many years, and their credibility is limited (Kihlstrom 1997; Kavirajan 1999; Loftus and Davis 2006; Lee et al. 2011; Cox and Barnier 2015). A comprehensive forensic psychiatric assessment is the best approach, although the consensus is that amnesia and expert testimony on the subject of amnesia remain a challenge in the forensic psychiatry arena.

LANDMARK CASES RELATED TO HYPNOSIS

People v. Shirley 1982

The Supreme Court of California excluded hypnotically refreshed testimony per se from witnesses. However, it explicitly excepted such testimony by an accused. The concern was three general characteristics of hypnotically enhanced recall that may lead to inaccurate memories. The subject becomes suggestible and may try to please the hypnotherapist with answers; the subject is likely to confabulate; and the subject experiences "memory hardening" that results in both true and false memories being held with great confidence and conviction making cross-examination more difficult.

State v. Hurd (Superior Court of New Jersey 1980)

In this case the victim, Ms. Jane Sell, was attacked in her own home early one morning but was unable to identify her attacker. Under hypnosis by a psychiatric expert Dr. Herbert Speigel, approximately 3 weeks after the attack, she stated while in a hypnotic state that her ex-husband, Mr. Paul Hurd was the assailant. This hypnotic trance was characterized by questioning by Dr. Speigel and a police detective involved in the investigation. In the post-hypnotic session Ms. Sell reported to be uncertain of the identification of the assailants, specifically her ex-husband. In this post-hypnotic session she was encouraged by both Dr. Speigel and the detective to "accept" the identification of the assailant. The legal issues in the case were as follows:

1. Whether the victim could be allowed to make an identification in court after she had not been able to do this prior to hypnosis
2. Whether hypnosis was a reliable tool the enhancement of memory
3. Whether the type of hypnotic interview in this particular case was unnecessarily suggestive so that the identification of the assailant from the hypnotic trance should be suppressed

In court, the defense motion, under the Fourteenth Amendment, was granted specifically to suppress the identification of the defendant by the victim who had undergone pretrial hypnosis. Dr. Martin Orne, an expert in hypnosis, testified at length about the inability to distinguish fact from fiction after hypnotic refreshment of memory, and that it was essential that the subject's statements be independently verified before they could be accepted as being reliable. He also testified that after hypnotic enhancement of memory, the subject of the memory enhancement would often report that the memory was clear and consistent and held with conviction, which was very different prior to memory enhancement. Dr. Orne recommended that the court adopt six safeguards related to memory enhancement. The safeguards were that the hypnosis should only be conducted by a licensed psychiatrist or psychologist trained in the use of hypnosis; that the qualified professional should be completely independent of either the defense or the prosecution; any information given to the qualified professional by law enforcement should be in writing; prior

to the hypnosis, the qualified professional should obtain a detailed description of the facts as the subject remembered them (in order to avoid adding new elements to the witness' recall by suggestion); all sessions between the hypnotic subject and the qualified professional had to be audiotaped at a minimum and videotaping would be preferable but not mandatory; and during the hypnotic session only the qualified professional should be present.

The decision of the court was that hypnotically refreshed memory should only be admissible on a case-by-case basis, and that the safeguards outlined by Dr. Orne should be used to decide whether hypnotically induced memory enhancement should be admissible.

Rock v. Arkansas (U.S. Supreme Court 1987)

Mrs. Vickie Rock was charged with manslaughter as a result of the homicide of her husband by shooting. This occurred against a background of marital discord, and there was a fight immediately prior to the shooting where Mrs. Rock told the police investigators that her husband had choked her and thrown her against the wall. As she could not remember the exact details of the shooting, her defense attorney recommended that she undergo hypnosis in order to refresh her memory. A psychologist was retained and made notes of her recollection in an interview prior to the hypnosis. This session and the hypnotic trance session were recorded. Mrs. Rock did not relate any new information during the hypnotic session, but after the hypnotic session she was able to recall that the gun misfired without her finger on the trigger. A firearms expert was retained by her defense counsel and found that the firearm was defective. The prosecutor objected to the hypnotically enhanced memory recall, and the judge ruled that Mrs. Rock held to limited testimony to what she remembered and stated to the examiner prior to being placed under hypnosis. Mrs. Rock was convicted of manslaughter and she was sentenced to 10 years of imprisonment. The case was appealed to the U.S. Supreme Court.

The court held that Arkansas' per se ruling excluding all hypnotically refreshed testimony infringed on the criminal defendant's right to testify on his or her own behalf, and this violated the defendant's Fifth, Sixth, and Fourteenth Amendment rights. The reasoning was that the majority of the U.S. Supreme Court pointed out that the right to present testimony is not unlimited, but restrictions imposed by the state may not be "arbitrary or disproportionate to the purposes they are designed to serve." Further, the state has an obligation to weigh the interest served by its rule (e.g., preventing erroneous evidence) to justify the limitations imposed on the defendant's constitutional rights. Further, the veracity of hypnotically refreshed testimony can be tested by cross-examination, which is an additional safeguard for the judicial process. The Arkansas rule failed because it did not allow the trial court even to consider the hypnotically refreshed recall, and therefore effectively prevented Mrs. Rock from describing the events of the shooting. In addition, the unreliability of hypnotically enhanced recall can be subject to verification by corroborating evidence and other methods of assessing the accuracy of testimony. The dissenting justices believed that the constitution should be construed so as not to intrude upon the administration of justice by individual states. The minority also noted that the majority opinion was equally sensible but did not believe it should be imposed on Arkansas.

BRAINWASHING

The *Oxford English Dictionary* records the earliest known English language usage of brainwashing by Edward Hunter, in *Miami News*, published on October 7, 1950. Brainwashing is defined as a forcible indoctrination to induce someone to give up basic political, social, or religious beliefs and attitudes and to accept contrasting regimented ideas (*Merriam-Webster Dictionary*). Brainwashing is also known as coercive persuasion. The term initially referred to the thought reform method used by Mao Tse-tung to eliminate "wrong thinking" from the Chinese people and instead convert them to communism. Torture was not part of this thought reform process, but the term gained wider usage later to include any methods used to change beliefs by force. Brainwashing is traditionally associated with extreme levels of physical torture and also psychological abuse, but the term has also been used in the context of individuals who join cults (West 1989).

Amnesty International was founded in London in 1961. It is a nongovernmental organization focused on human rights. The objective of the organization is to conduct research and generate action to prevent and end grave abuses of human rights, and to demand justice for those whose rights have been violated. Amnesty International regularly identifies nations that are engaging in torture of prisoners, even before these individuals are charged or sentenced. These methods are not necessarily related to brainwashing in its original meaning. These abuses range from general neglect to extreme physical torture. In recent years, Amnesty International has been involved in broader causes of human rights violation (retrieved from https://www.amnesty.org/en/). Although the term *brainwashing* is at times used almost interchangeably with torture, its original meaning involved the goal of changing one's beliefs and did not involve obtaining information from the individuals subjected to its methods. One of the most prominent examples in history is the Nazi indoctrination, considered one of the most effective brainwashing techniques, with a single focus on racial hatred (Voigtländer and Voth 2015).

SUMMARY KEY POINTS

- Amnesia is a common presentation in the forensic setting. Dissociative amnesia, substance-induced amnesia, and malingering are the most common causes of amnesia in the forensic setting.

- Although relatively uncommon, medical causes of amnesia, including neurocognitive and sleep disorders, should always be considered.
- Hypnosis and amytal interviews are not recommended in forensic psychiatric evaluations as they may create distortions in recollection as well as create implanted memories, and are of very limited use in a court setting.
- Brainwashing is a form of coercive persuasion to changes one's basic beliefs, usually to accept a different set of values. The term has been broadened and has been used to describe certain aspects of cults as well as situations with extreme physical and psychological torture.

Culture and forensic psychiatry

ALEXANDER I.F. SIMPSON AND SUSAN HATTERS-FRIEDMAN

INTRODUCTION

We live in complex societies. There is great variety of income, race, ethnicity, and culture within them. The problems that forensic psychiatry is focused on, mental disorder and crime, are not evenly distributed within our societies. These problems afflict communities in different ways, and to varying degrees.

We often do not perceive these differences, or do not regularly reflect on why they might exist. We are immersed in our own values, patterns of life, patterns of behavior, and assumptions about the world. We are aware of difference but do not necessarily understand it. We can make assumptions about others, and about the meaning of thoughts, behaviors, or attitudes. We call people "individuals," "clients," "defendants," "evaluees," "patients," or "the accused."

Because of the diversity of our societies, many forensic assessments are cross-cultural, whether across economic or cultural difference. We commonly assess or treat people from other cultural groups. Further, adopting the same approach to all people ("color blindness") may not appreciate the subtle variances in need or biases that may manifest. For instance, pathways for people into forensic care may be different between ethnic groups (Flora et al. 2012). There is much evidence that race and culture may impact the needs people present with (Leese et al. 2006), how "dangerous" they are rated (Vinkers et al. 2010), or their access to services (Simpson et al. 2003). Are these observed differences due to differing socio-demographic experience because of structural or historical differences in society? Or do they stem from erroneous assumptions by mental health institutions and practitioners? These questions are too complex for this chapter to answer. But we consider how forensic practitioners may address these questions in their own practice.

In essence, forensic psychiatry is a process of understanding another person: understanding his or her disease, illness, disability, motivations, behavioral patterns, and the likelihood that he or she may behave in particular ways in the future. It is also about opining, recommending, offering, providing, or overseeing treatment. Treatment is aimed at making things "better." We assume that we share a similar understanding of "better," but this may not always be so.

The purpose of this chapter is to assist the forensic practitioner in understanding the impact of culture on his or her individual practice. This includes both forensic evaluation and treatment. It describes how cultural formulation can improve and inform forensic practice. It introduces clinically relevant concepts of culture and race, and looks at the application of tools to assess the impact of the cultural meanings and differences on a person's assessment and treatment in forensic practice.

WHAT DO WE MEAN BY CULTURE?

Culture was a term first coined by a German scholar in the late eighteenth century to describe the achievements of particular civilizations. The definition of culture has developed through time to encompass the myriad behaviors, attributes, practices, rituals, traditions, and their attached meanings for different social groups (Tseng et al. 2004). The National Institute of Mental Health's (NIMH) Culture and Diagnosis Group described culture as the "meanings, values and behavioral norms that are learned and transmitted in the dominant society and within its social groups. Culture powerfully influences cognition, feelings and self-concept as well as the diagnostic process and treatment decisions" (see Lu et al. 2008, 118; Aggarwal 2012).

Race, on the other hand, was originally conceptualized one dimensionally as a biological construct, referring only to the phenotypic traits of groups of people who may have shared similar physical features, such as the same color skin, eyes, or hair. Society responds to people of certain "racialized minorities" or "people of color" in stereotypic or prejudiced ways, making, as Henry Louis Gates noted, race "a lived experience." Race-as-experience therefore is more an artefact or by-product of socio-economic and political circumstances (Tseng et al. 2004).

Ethnicity acknowledges the critical roles of language, culture, and history as part of the formation of identity (Fernando 2003) and refers to shared belief systems

and cultural practices among groups that are learned. Ethnicity also refers to the way people perceive themselves, therefore influencing self-concept and identity formation (Fabrega 2004).

Indigeneity, that is, being an indigenous person, is a particular cultural/ethnic experience, an epistemic class of its own. For indigenous people, identity is fundamentally interwoven in the relationship to their particular place, land, spirituality, and history. As a cultural group they have no other home than the place they live in. They are the people of the land whose identity has often been threatened grievously by colonization and economic development. They are overrepresented in forensic populations.

Culture can affect the symptoms a person presents with and may shape the form of illnesses such as schizophrenia (Myers 2011). Social context may make it easier or harder to engage in social supports. Cultural change brought about by colonization, development, or migrancy affects populations and individuals. For instance, while first-generation migrants may be at greater risk of developing a psychotic illness, there is clear evidence that second-generation immigrants are at highest risk of psychosis. This is rather than pre-immigration issues or diagnostic bias as being of greatest relevance. The reason for one's migrancy may play a role, with refugees recently shown to be at greater risk of developing a psychotic illness than other migrants (Anderson et al. 2015). Context is also important; remarkably, if one migrates but lives in a community with more than 25% of one's own ethnic group, then one's risk of psychosis is lowered. Some evidence of diagnostic misunderstanding may play a part in some settings (e.g., Lewis-Fernández et al. 2009). Cultural practices or rituals that may help deal with distress may be lost in the migration or assimilation processes. The new institutions that people encounter frequently fail to help people integrate and manage their distress or their psychotic experiences into their personal narrative and cultural worlds (Kirmayer 2012). The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*) has recognized these issues in moving away from the outdated concept of "cultural-bound syndromes" to "cultural concepts of distress." Cultural concepts of distress are described as including syndromes, idioms of distress, and their explanations (or perceived causes). Symptom clusters co-occurring among a cultural group would be included in syndromes. Cultural idioms of distress are shared ways of discussing and experiencing distress, such as discussing "nerves." Finally, cultural explanations or perceived causes are attributions and explanatory models with a recognized meaning behind symptoms. The authors of *DSM-5* note that all distress is "locally shaped" (American Psychiatric Association 2013).

CULTURE OF PSYCHIATRY AND LAW

Discussion of culture is often framed in terms of the difference between the assessor and the assessee, but discussion of culture *in* law and psychiatry must mention the culture *of* the law and psychiatry. Law and systems of justice are themselves cultural paradigms. We recognize that attorneys, probation officers, judges, experts, witnesses, or jurors all bring their own preconceived notions, attitudes, and value systems to the process of justice (Tseng et al. 2004). These preconceived notions affect their relatedness to others, their understanding about why people may behave in certain ways, and the culpability of people for that behavior. The fact that such people come together in this way is a cultural construct: that people must be held accountable for their actions, that they are innocent until proven guilty, and that they have a right to remain silent, etc. Further, the cultural idiom of McNaughton's rules is a very good example: as a culture we exempt some people who have performed an act from culpability, because we recognize something called a disease for which a person is not morally accountable. This is not a universal human understanding. A psychiatrist must try to "fit" a person's experience into such a set of rules (Fabrega 2004), but is also a participant in this culturally defined and sanctioned paradigm. Further, many players in the forensic process (judges, counsel, psychiatrists, psychologists) tend to come from privileged parts of society, whose experience of race and discrimination is very different than that of the poor evaluee of minority ethnicity from an educationally and socially deprived background.

The culture of the forensic assessor is likely to at least in part include the cultural influences of the dominant society; the cultural identity and background of the assessor; the institutional culture of the clinic, hospital, or organization, and the professional association with which the assessor is associated; and the professional cultures of biomedicine and psychiatry (Mezzich et al. 2009).

Psychiatry values that its learning is evidence based and is developed within the framework of a scientific or positivistic approach. Cultural understandings are formed differently from narrative and shared understandings of personal and community origins and beliefs. As Whitley (2007) states, both forms of understanding of people are ultimately aimed at the same thing: best outcomes for patients, but by different routes. Evidence-based approaches seek knowledge via the normothetic knowledge of science, while cultural or personal narratives do so via the idiographic understanding of the individual person's life, origin, and values. Care must be tailored to fit such values on the basis of best evidence. Norko (2005) has argued that forensic ethics are inextricably linked to compassion for the person under evaluation, including a comprehensive understanding of their life, narrative, and values. Griffith et al. (2010) construct the forensic report as a cultural narrative to give contextual meaning to the behavior and beliefs of the evaluee. They advocate that the understanding must then be related to the legal test in question. They argue that this idiographic narrative generates the possibility of empathic or imaginative understanding of the person not available in the more narrowly conceived forensic practice.

CULTURAL COMPETENCE AND FORENSIC PSYCHIATRY

We practice this work in the presence of diversity. To live effectively together, societies require shared rules to govern us all. Forensic psychiatry exists at the nexus between these forces: applying evidence-based knowledge, combined with an essential understanding of the narrative of the person being assessed or treated, appreciating who they are, and relating these themes to the shared sets of rules that govern societal responses to behavior (Fabrega 2004). What are the skills necessary for this task?

The ability to understand the person's own narrative is a skill that requires cultural sensitivity on the part of the forensic practitioner, and the proper questions and approaches to assist in exploring a person's experience comprehensively. The key skill that practitioners need to possess has been widely referred to as *cultural competence*.

Kirmayer (2012) defined "cultural competence" as a set of attributes that the practitioner possesses (see also Mezzich et al. 2009). These include self-awareness regarding one's own cultural beliefs and origins, and how those attributes may impact clinical interactions. Second, an evaluator requires some core knowledge about the socio-ethnic group of the person being assessed. If the evaluator is not knowledgeable in this area, he or she must recognize his or her limitations and seek the input of persons knowledgeable in those areas. Third is the area of skills competency, where one can successfully apply one's own knowledge and clinical skills in a culturally appropriate manner in an attempt to understand and formulate the relevant issues for the situation to be understood.

Kirmayer (2012) proposes that "cultural competence" may work at multiple levels, not only that of the individual practitioner, but also at an institutional and technical level. The ways law is structured and practiced may be examples of the institutional and technical aspects of interactions that may present challenges of cultural bias. Institutions may, for example, attempt to positively create roles to enhance "ethno-cultural matching," such as employing staff representative of the ethnic mix of the community being served or creating policies or processes to engage interpreters and cultural consultants to assist in care. Staff training and supervision, such as awareness, knowledge, and sensitivity training, are widespread and important steps to improve the cultural competence of a clinical program and individual staff members.

Mossman et al. (2007) in the American Academy of Psychiatry and the Law (AAPL) guidelines for competency to stand trial evaluations describe cultural competence explicitly as it is relevant to forensic practice and case formulation. They state that culturally competent evaluations require understanding of the context of the person and his or her life and acceptance of the person's cultural identity. They usefully underline the knowledge, skills, and attributes of the assessor with particular emphasis on the interactive style, bias, transference, and countertransference that can emerge in a forensic setting, citing the Stone, Appelbaum, and Griffith debates as a clear example of these competing forces.

APPLICATION OF CULTURAL COMPETENCE TO FORENSIC TASKS

Cultural competence is the first key skill a forensic practitioner must possess. To help construct a consistent and comprehensive approach to performing a culturally informed assessment, a few simple tools are of value. Indeed, tools to assist any practitioner in culturally sensitive interviewing and formulation are not new. Some of the most helpful and simple guidance came from Arthur Kleinman (1980) who suggested asking eight questions to gain access to the person's own understanding of why he or she is ill and what that means for that person (see Table 76.1).

The forensic assessor can see how these questions capture aspects of a person's beliefs about himself or herself and his or her situation, and get insight into the person's illness, its meaning, and factors relevant to treatment and future outcomes. Substituting risk or offending for illness in the questions clearly has useful application in considering a person's self-understanding about the issues being assessed.

The diagnostic nosologies of *DSM* and International Classification of Diseases (*ICD*) were developed to be "culture free," though both saw culture as very important in understanding the manifestations of distress of a person. Although *DSM-IV* rejected including a cultural axis (Mezzich 1995), it did give guidance about the development of a cultural formulation. It recommended that the following elements be addressed: the cultural identity of the individual, cultural explanations for the person's illness, cultural factors related to the psychosocial environment and levels of functioning, cultural elements in the relationship between the person and the clinician, and the overall cultural assessment for diagnosis and care.

Table 76.1 Kleinman's questions regarding the evaluee's understanding of illness and its meaning

1. What do you think has caused your problem?
2. Why do you think it started when it did?
3. What do you think your problem does inside your body?
4. How severe is your problem? Will it have a short or long course?
5. What kind of treatment do you think you should receive?
6. What are the most important results you hope to receive from this treatment?
7. What are the chief problems your illness has caused you?
8. What do you fear most about your illness/treatment?

Source: Adapted from Kleinman A. 1980. *Patients and Healers in the Context of Culture*. Berkeley: University of California Press.

Lewis-Fernández et al. (2014) describe how the cultural formulation structure of *DSM-IV* has been operationalized into a structured interview entitled the Cultural Formulation Interview (CFI). *DSM-5* published the CFI, a 16-question semi-structured assessment that can be used to obtain information about culture, including cultural definition, perceptions of cause, and the cultural factors affecting coping and help-seeking. The *DSM-5* argues that cultural concepts are important in clinical psychiatry to avoid misdiagnosis, obtain further clinical information, and improve rapport and efficacy. There are now a small number of studies giving modest support to the improvement in diagnosis and treatment understanding that can come from the use of the CFI in consultation or assessment services. For instance, Adeponle et al. (2012) found that when the CFI guided a consultation service assessment, misdiagnosis that had previously occurred in 60% of these referrals were much more clearly understood after the use of the CFI among immigrant groups. Aggarwal (2012) describes how the CFI can be applied in forensic settings, pointing out that this culturally informed interviewing is often absent in standard forensic texts.

The CFI lends itself very well to structured assessment or consultations. There is as yet no published evidence of its use in a forensic setting, though this is only a matter of time. Interestingly, Kapoor et al. (2013) have adapted the CFI for prison settings in the United States and describe it as being valuable in correctional psychiatric practice.

Mezzich et al. (2009) provide useful guidance for clinicians performing a culturally sensitive assessment. In addition to taking the usual care in the clinical interview, they emphasize the importance of taking care over expectations for greeting formalities, dress, and interpersonal distance. If using an interpreter or cultural broker, one must ensure his or her role is clear and acceptable to the person in advance. In the body of the interview itself, it should be ensured the interviewer shows appropriate respect for the cultural understandings and expectations of the person, and gives the person ample opportunity to express himself or herself. A very rote or rigid interviewing style may not communicate this level of interest or concern. It is often wise to seek clarification to ensure the person's perspective is properly understood.

The AAPL guidelines on fitness/competency to stand trial evaluations (Mossman et al. 2007) again deserve particular mention. The guidelines contain comprehensive guidance on cultural issues in fitness evaluations. They consider carefully the cultural values inherent in fitness to stand trial and the likely identification of the forensic assessor with those values. These values include the concept of procedural fairness, including the right to understand and confront one's accusers, to interact with counsel to assist with this, and the right of the defendant to express his or her own opinion and make a plea on the basis of his or her own interests. They point out that these are not necessarily shared in common by defendants of other cultures, who may not have a tradition of raising one's voice against authority or senior cultural or family leaders. Therefore, the defendant may not engage counsel in his or her defense, not because of problems of psychopathology, but because of cultural expression. The guidelines encourage the use of self-reflection by the clinician to assist in the avoidance of bias (including previously unrecognized bias).

CULTURE AND FORENSIC TASKS

Cultural assessment and formulation

Guided by the tools and questions described above, the psychiatrist must also know the limits of his knowledge, and when to seek consultation. Forensic psychiatrists need to identify the traditions, values, and culturally syntonic beliefs of the evaluee, and then consider their relevancy to the specific consultation questions (Glancy et al. 2015; Aggarwal 2012). Psychiatrists should ask defendants about how they self-identify rather than merely making assumptions, based on appearance (Aggarwal 2012). Cultural distinctiveness should be considered in forensic evaluations (Kirmayer et al. 2007); however, the risk of stereotyping evaluees rather than truly understanding their background must not be ignored. "Stereotyping provides a simplistic and distorted picture of the social and individual aspects of a person and in itself can have negative consequences for mental health" (Mezzich et al. 2009, 393).

Mezzich and colleagues note that "culture deeply informs every aspect of life and health" (Mezzich et al. 2009, 384), and they have offered an approach to the cultural formulation as part of clinical care. The intent was for the cultural formulation to coexist with a *DSM* formulation, and to be a narrative. The psychiatrist "should strive to describe the person as a cultural being identified with particular values, traditions and orientations….although culture and ethnicity identify groups this does not mean that all members of a group believe or behave in the same way; ideas and values associated with cultures and ethnicities may be highly variable owing to gender, age cohort, socio-economic class, geographic region (rural versus urban), religious factional differences and personal preferences" (Mezzich et al. 2009, 392). Ajaz et al. (2014) described the cultural formulations for forensic psychiatry as including an understanding of the following four factors: the evaluee's cultural identity, cultural explanation of illness, cultural factors relevant to psychosocial environment and functioning, and cultural elements of a physician–patient relationship.

Interpreters and cultural consultants

Interpreters are strongly recommended if the evaluee's primary language is not English, and if the evaluator is not fluent in the evaluee's primary language. Accuracy in evaluations is of great importance (Maddux 2010). Difficulties with interpretations of meaning across languages and cultures can lead to misinterpretations (Mossman et al. 2007). However, the use of an interpreter can be fraught.

Whenever possible, a court-approved interpreter with some background in mental health should be utilized in forensic evaluations (Maddux 2010; Tseng et al. 2004). The interpreter must understand the difference between linguistic and conceptual interpretation.

The psychiatrist should attempt to speak with the interpreter in advance, to explain the differences between forensic and general evaluations. Also in advance, the evaluation room should be set up such that the evaluator can have eye contact with the evaluee (Committee on Cultural Psychiatry, Group for the Advancement of Psychiatry [GAP] 2002). The interpreter should give verbatim translations, because other translation choices could cause distortion of meaning or loss of nuance (GAP 2002; Mossman et al. 2007; Glancy et al. 2015). Problematically, some subtleties of language and meaning can easily be lost in this process. Asking questions in different ways may assist in exploring an issue and checking out whether the correct understanding has been gained.

Mezzich et al. (2009) caution that while understanding of families increases cultural understanding, their perceptions "do not constitute the ultimate truth about the patient's condition, but provide a complementary perspective" (Mezzich et al. 2009, 389). Family members may offer to provide interpretations, but this could easily negatively impact the assessment—there are many reasons why an evaluee may not share the full story with a family member present (GAP 2002). Similarly, when performing an interview in a smaller community, it becomes more likely that the interpreter and evaluee may know each other from contexts other than the evaluation (Maddux 2010).

If the interpreter is knowledgeable not only about language and mental health, but also about culture (Tseng et al. 2004) then this is more ideal. For example, a Spanish interpreter from South America or Mexico or Puerto Rico may have a different cultural background than a Spanish interpreter from Spain, and it would be optimal in order to help situate the evaluee in terms of culture. Additionally, cultural consultants can be engaged in order to help the evaluator understand the meaning of specific actions to members of a specific culture. One must beware the risk of stereotyping. Cultural analysis with the assistance of a cultural consultant can help decrease misunderstandings and the evaluator's potential prejudged notions.

Describing the narrative

Forensic psychiatrists, as well as their evaluees, have had cultural and religious "personal experiences that have contributed to the shaping of [our] moral life" (Griffith 2005, 372) as Griffith highlighted in relation to the Stone/Appelbaum debate about the role of psychiatrists in the courtroom. This debate underlines that the forensic practitioner must be aware of cultural impact on transference and countertransference in approaching a forensic evaluation. Specifically, one must use caution not to overidentify with those from one's own cultural group, such that one may lose objectivity. Care should be taken that the goal of describing to the court the meaning of behavior within the evaluee's cultural context does not distort the truth. At the other end of the spectrum, one must use caution not to incorrectly diagnose those from other groups (Mossman et al. 2007).

Fabrega (2004) described the clinician as attempting to fit a cultural understanding of the defendant into the rules of law. He described that determining "culpability of homicide is entangled in questions about norms, values, competence, deception, responsibility, and blame" (Fabrega 2004, 179). However, the psychiatrist must also consider his or herown cultural beliefs. The psychiatrist too is part of the process of cultural understanding of the law.

Griffith (2005) has described that the forensic report should be a cultural narrative that helps give contextual meaning to behavior and beliefs. This can be tied in to legal test at issue. Narratives generate the possibility for greater empathic and imaginative understanding.

These debates have described that forensic psychiatrists' ethical tenets include striving for objectivity but also for understanding. When the evaluee is from another culture or holds different religious beliefs than the psychiatrist, it is particularly important to consider the potential for bias and countertransference that can affect the evaluation. One should consider cultural consultations in complex evaluations where culture is at issue (Hicks 2004; Boehnlein 2005). Further, even in "run-of-the-mill" cases in which the evaluee is of a different culture, it makes sense to examine one's own biases, unexplored fears, and the role of countertransference (Glancy et al. 2015; Mossman et al. 2007; Mezzich et al. 2009). To be culturally competent, one must not only respect cultural differences but also consider how these differences affect forensic evaluation, and frequently self-assess one's own assumptions. One must be aware of one's fears and prejudices. Forensic psychiatrists should strive to understand the evaluee's culture and values, how distress may be expressed within a culture, how culture may affect communication, and how racism and power dynamics impact relationships.

CULTURE IN SELECTED SCENARIOS

Fitness/competency to stand trial

AAPL's competence to stand trial guidelines provide an excellent discussion of cultural considerations in these evaluations (Mossman et al. 2007). They describe that most psychiatrists identify with the dominant culture's view, including that criminal proceedings are fair and just. The guidelines note: "competence to stand trial thus embodies a cultural notion that the legal system is reasonably fair, that accused persons will get fair treatment and a reasonable chance to defend themselves, and that the dignity and fairness of the criminal proceedings are vindicated when an accused person is a capable adversary of the prosecution" (Mossman et al. 2007, S29).

Some cultural values are inherent in competency assessments, and the forensic psychiatrist likely identifies with

those values. These include procedural fairness (the right to confront one's accusers, to interact with counsel to assist with this, and the right of the individual to express their own opinion). These values are not necessarily shared by defendants of other cultures, who may not have a tradition of raising one's voice against those in authority, such as senior cultural or family leaders. For example, they may not engage others in their defense, not because of psychopathology, but because of cultural expression. Further, there are reasons other than mental illness why those from the nondominant culture may be suspicious of the legal process.

Insanity/criminal responsibility

Understanding culture allows us to understand how behaviors leading to legal charges originated and better understand their meaning. The *McNaughton* rules are embedded in Anglo-American society (Fabrega 2004). Whether one sees one's acts as wrong has cultural underpinnings as well (Tseng et al. 2004; Glancy et al. 2015), because what is considered wrong in one culture may not be considered wrong (or indeed may be considered right) in another culture. This difference may receive more weight in specific jurisdictions in which the "moral wrongfulness" is considered rather than merely the "legal wrongfulness."

One must attempt to grasp an understanding of the defendant's world view. Considering culture can help us understand personality prior to the offense, development, and meaning of education, as well as help conceptualize whether the offending was related to mental illness (Ajaz et al. 2014). The defendant's actions should be considered within the context of his or her own culture in attempts to understand the act. This can help the evaluator understand the defendant's reasoning (Kirmayer et al. 2007; Glancy et al. 2015; Aggarwal 2012). This in turn will help in assessing culpability and knowledge of wrongfulness (Boehnlein et al. 2005; Kirmayer et al. 2007; Aggarwal 2012). A cultural perspective in a sanity evaluation helps place the defendant's actions in context (Ajaz et al. 2014)

Kirmayer and colleagues noted, "In many cases, it is not whether the act was committed that is in question, or the level of intent or control, but what its meaning and significance is to the defendant. Culture frames problems and presents us with the categories and concepts through which we organize and understand our own actions" (Kirmayer et al. 2007, 100). It is important for the forensic psychiatrist to help the finder of fact (judge or jury) understand the role of culture in the offending. Cultural formulation may improve both understanding and empathy from the court.

The "cultural defense"

Each of our cultures shapes our identity, emotional reactions, thought processes, motives, and intentions. Debate exists about a cultural defense, regarding whether it is just to judge someone based on the values and laws of a society that is foreign to him or her (Ajaz et al. 2014). This is in contrast to the importance of maintaining integrity of the law. Cultural defenses can restrict the fundamental fairness of the law by introducing inconsistent rules for different groups of people (Kirmayer et al. 2007). Few groups have wanted the law to apply inconsistently to them and to so be excused of societal accountability, and thus the cultural defense is rarely raised, and likely properly rarely applied. Most groups desire to live by common values (Kirmayer et al. 2007).

Thus tension exists between understanding the person and his or her culture, and the universality of the rules against which people should be judged in our society. It is critical that we do not stereotype but still that we note cultural distinctiveness. Helping the court to understand the defendant's culture, through the cultural formulation, should lead to the fairest outcomes, without a change of the law depending on the defendant.

Culture and sentencing

Although a "cultural defense" is rarely used (and likely appropriately so), demands for culturally informed sentencing are much more common in international settings, particularly in relation to colonized indigenous peoples. Sentencing may be informed by cultural issues among New Zealand Maori (Mead 2003). For indigenous Canadians, this has been set out in a finding of the Supreme Court of Canada (in *R v. Gladue*), and now in the Criminal Code of Canada. In order to address historical overrepresentation of Canadian aboriginals in the justice system, CCC s718.2 e requires the sentencing court to pay particular attention to aboriginal offenders' circumstances. The unique background factors of the defendant (e.g., poverty, poor education, substance use, high crime communities) are considered along with the sentencing options given the index offending. Specifically, what is the right sentence for this offender committing this offense, harming this victim, within this community? Aboriginal status alone, however, should not be a mitigating factor. Restorative sentencing is encouraged, with an overall aim to reduce the use of incarceration. Traditional beliefs were strongly anchored in concepts including restitution and reintegration, but also taking responsibility for one's actions, and facing one's victims and the community. Restorative justice may be punitive as well as restorative. In *R v. Gladue*, the Supreme Court of Canada required that sentencing judges must consider the unique systemic and background factors of the aboriginal defendant in passing sentence. The court was clear that aboriginal communities did not reject the need for punishment and deterrence, but rather that a sentence should fit the needs of the person and his or her community. In sentencing, caution needs be used that culture is not a reason for discrimination either for or against a defendant.

Culture and risk assessment

Risk assessment requires both evidence-based (normothetic) analysis and risk formulation (ideographic) components. Cross-culturally, there are problems with both of

these processes. There is very limited cross-cultural data on many of the risk tools commonly used. For instance, in noting this deficiency, Douglas and Reeves (2010) advise that caution must be exercised when using the Historical Clinical Risk Management-20 (HCR-20) for populations on which it has not been normed. They also state, though, that the core domains of risk being measured have been observed as relevant for violence prediction in many settings, so are likely to be of importance cross-culturally. The final risk judgement and risk formulation offer the opportunity to appropriately weight factors relevant to a particular cultural context. This requires the skills of cultural and risk formulation, to ensure that racial stereotyping does not bias the assessor because of a failure to understand this person, rather than seeing this person as representative of a particular group. Racial bias or inaccuracy had been noted in diagnosis (e.g., Adeponle et al. 2012) and in application of dangerousness criteria (Vinkers et al. 2010). Without cultural formulation being built into risk assessment and cross-cultural testing of the assumptions in risk assessment tools employed, similar risks of cross-cultural misinterpretation may confront the forensic practitioner.

Child protection and child custody

Similarly, the psychiatrist should examine his or her own potential biases and countertransference in civil cases. In cases of child protection, care must be taken about the meaning of actions within a certain cultural community. What is considered neglect in one situation may be appropriate parenting behavior in another. For example, while in many cultures, children may babysit other children by the time they are 12, in New Zealand, it is considered neglect to leave a child under 14 without supervision. In America, the Indian Child Welfare Act requires that different standards be met for native American children and families than other Americans. This includes before a Native American child can be placed with a non-Native American family, within various custody proceedings including foster care, adoption, and termination of parental rights (Wills and Norris 2010).

SUMMARY KEY POINTS

- Forensic psychiatric assessments often occur cross-culturally.
- Those of minority ethnicities are consistently overrepresented in the legal system and correctional populations around the world.
- Culture may affect the manifestation of symptoms that an evaluee presents with, and their meaning.
- Cultural formulation may improve both understanding and empathy. The cultural formulation can be narrative and coexist with *DSM* diagnoses.

Geriatric forensic psychiatry

BRIAN A. FALLS, GEN TANAKA, AND HAROLD J. BURSZTAJN

INTRODUCTION

As the subspecialty of forensic psychiatry continues to grow (Engstrom 2009), geriatric forensic psychiatry (also called "geroforensic psychiatry") will foreseeably become a field of ever-increasing import for two key reasons. First, the elderly population of developed nations is rapidly rising. In the United States, for instance, the elderly population will likely double between 2000 and 2050 (U.S. Census Bureau 2008). Second, medical and psychiatric knowledge are increasing at such a rate that by 2020, medical knowledge might double every 73 days (Denson 2011).

In this chapter, we discuss forensic psychiatric principles commonly encountered with a geriatric population; the geroforensic evaluation; capacity evaluations commonly performed with elderly evaluees; elder abuse; geropsychiatric malpractice issues; malingering of neurocognitive disorders; and older adults in the criminal justice system.

FORENSICALLY RELEVANT MEDICAL AND PSYCHIATRIC PROBLEMS IN OLDER ADULTS

Psychiatric disorders are more common among older individuals than younger individuals (Jeste et al. 1999). Substance use disorders appear to be increasing among older adults in the United States. Researchers forecast that substance use disorders in this population will increase by 70%, even when adjusted for overall growth of the elderly population segment (U.S. Census Bureau 2006; Han et al. 2008).

Even more forensically relevant to the older population than substance use disorders and noncognitive psychiatric disorders are *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*) Neurocognitive Disorders (American Psychiatric Association [APA] 2013). Cognitive domains that can be impacted by these disorders include complex attention, executive functioning, memory, language, perceptual–motor skills, and social cognition. *DSM-5* taxonomy aside, forensic evaluators need to broadly consider "cognitive" impairment and avoid the artificial division between disorders of cognition and feeling (Bursztajn et al. 1991). About 30%–80% of patients with neurocognitive disorders can have behavioral and psychological symptoms of dementia (BPSD) (Margallo-Lana et al. 2001; Lyketsos 2002), which can include delusions, hallucinations (usually visual), agitation, aggression, and disinhibition (Taylor et al. 2012).

Neurocognitive disorders are often irreversible and tend to worsen over years. Yet there are some fairly common medical, affective, and social-context issues that can interfere with capacity that are potentially reversible. These factors include delirium; pseudodementia; medications/polypharmacy; isolation; and caregiver, family, and institutional dynamics relative to the increased dependency of the fragile elderly.

Pseudodementia refers to cognitive deficits that mimic dementia and are due to another condition, usually a psychiatric disorder. Some disorders that can impair cognition in such a manner include mood disorders, psychosis, dissociative disorders, conversion disorder, and Ganser syndrome (Dobie 2002). In particular, mood disorders can appear exquisitely similar to dementia, as the two types of conditions share symptoms of impaired concentration, apathy, anhedonia, amotivation, impoverished speech, changes in appetite, changes in sexual interest, and sleep disturbances. With the fragile elderly, affect-based impairment may be so difficult to disentangle from cognitive-based impairment as to highlight the limitation of the cognitive/affective distinction perpetuated when current diagnostic systems are mechanistically translated into formulations of capacity (Bursztajn et al. 1991).

Polypharmacy, along with medication use in general, is a common cause of cognitive problems in the elderly (Sergi et al. 2011). One out of six individuals age 65 or older is taking 10 or more medications (Guthrie et al. 2015). The sheer number of medications consumed by older adults is complicated by pharmacodynamic and pharmacokinetic inefficiencies that accompany aging (Taylor et al. 2012). Certain medical conditions, whose incidence increases

with age, can also reversibly interfere with an individual's cognition.

SPECIAL CONSIDERATIONS FOR THE GEROFORENSIC EVALUATION

General considerations

As with any psychiatric interview, in the geroforensic evaluation, evaluators should ask open-ended questions and take time to genuinely listen. All forensic evaluees should be treated with respect (Appelbaum 1997) and, especially with larger evaluator–evaluee age discrepancies, a respectful approach can help build rapport (MacKinnon et al. 2006).

Forensic psychiatrists evaluating older adults should be mindful of hindrances to effective communication. Perceptual problems, such as hearing and visual impairments, can further complicate communication with evaluating psychiatrists by making elders feel embarrassed and disoriented. Especially in hearing-impaired evaluees, psychiatrists should use simple sentences and provide sufficient time for responses to inquiries. Evaluators should speak in a loud, clear voice; face evaluees so they can read lips; and sit close enough for evaluees to hear (Gerontological Society of America 2012; Blazer 2014, 13).

Older adults tend to have less positive attitudes toward mental health care than younger populations (Farberman 1997), which can also interfere with communication. Many older people experience relatively high anxiety levels yet do not complain about it. Older people may be more hesitant to reveal their affect verbally and more likely to be cautious in their responses (Blazer 2014, 12), so nonverbal communication may be especially important. Some other common reasons for guardedness include a desire to maintain independence, especially in capacity evaluations; reticence regarding finances or relationships; anxiety about or denial of mortality; and fear of loneliness or abandonment (Sprehe 2003).

Transference and countertransference

As with any psychiatric interview, countertransference and transference occur in the geropsychiatric forensic interaction. Forensic psychiatrists may misperceive older evaluees due to cultural ageist biases, their own fears of aging and mortality, or previous experiences with parents (Myers 1986; Blazer 2014, 12).

Similarly, evaluees may experience transference (Myers 1986). For those aged who are cognitively impaired, their perceptions of evaluating psychiatrists may be even more prone to distortion, based on prior experiences, than those of younger evaluees. Evaluees with mild neurocognitive impairment usually develop a transference consistent with their underlying lifelong character traits. Contrarily, individuals with major neurocognitive disorder may relate to psychiatrists in ways that have more to do with their organic illness than enduring personality patterns (MacKinnon et al. 2006).

Presence of third parties

Some frail elderly individuals will seek reassurance by requesting that family, friends, or other "familiar faces" be present during interviews. Family and friends may also insist on their being allowed to be present during evaluations. As with all forensic psychiatric interviews, evaluators should nonetheless resist temptation to include a third party. Doing so can distort and complicate interviews (Gavett et al. 2005). For instance, evaluees with neurocognitive disorders might seek clues in others' facial expressions and might, for example, confabulate based on this. Especially in undue influence evaluations or cases of suspected elder abuse/neglect, they may choose not to disclose certain information based on others' nonverbal cues, intimidating or otherwise. In clinical geriatric psychiatric evaluations, family or friends may provide much of the history while the patient is present in the room (Sadock and Sadock 2014). During a forensic evaluation, however, evaluators should not obtain collateral information with evaluees present (Simon 1996). Instead, collateral data should be gathered outside the setting of the forensic psychiatric examination.

The problem of dual agency

A frequent problem in general forensic practice, the "dual agency" issue is even more often encountered in geroforensic examinations and can result in serious bias (Strasburger et al. 1997). Treating physicians may have an interest in maintaining the therapeutic alliance with elderly patients and in avoiding a potential "shoot the messenger" reaction associated with the grief of decreased autonomy. For this reason, they are usually less likely to find examinees incapacitated, although the pendulum can also swing in the opposite direction.

CAPACITIES

Incapacity to make and articulate specific decisions is a problem that disproportionately affects older adults (Moye and Marson 2007). One group writes that "as our society ages, clinical assessment of higher order functional capacities has become increasingly important. In areas like financial capacity, medical decision making capacity, medication compliance, and driving, society has a strong interest in accurately discriminating intact from impaired functioning" (Marson et al. 2000). Below is a nonexhaustive list of commonly evaluated capacities in the elderly population. Most U.S. jurisdictions now legally recognize capacities as situation or task specific (Smyer 2007). Because the legal criteria differ between jurisdictions, here we offer only general legal definitions. It is important for geropsychiatric evaluators to familiarize themselves with their local laws.

Just because an evaluator diagnoses an individual with neuropsychiatric illness does not mean that the individual is incapacitated. Furthermore, there is no level of neurocognitive impairment that necessarily precludes any

Table 77.1 Some capacity assessment tools

Medical decision making	Advance directives	Independent living	Financial decision making
MacArthur Competence Assessment Tool–Treatment (MacCAT-T)	Competence Assessment Tool for Psychiatric Advance Directives (CAT-PAD)	Adult Functional Adaptive Behavior Scale (AFABS)	Financial Capacity Instrument (FCI)
Aid to Capacity Evaluation (ACE)	Hopkins Competency Assessment Test (HCAT)	Revised Direct Assessment of Functional Status (DAFS-R)	Hopemont Capacity Assessment Interview (HCAI)
Assessment of Capacity to Consent to Treatment (ACCT)		Multidimensional Functional Assessment Questionnaire (MFAQ)	
Capacity Assessment Tool (CAT)		Philadelphia Geriatric Center Multilevel Assessment Inventory (MAI)	

specific capacity. On the other hand, two different diagnoses, such as a neurocognitive disorder due to Alzheimer's disease dementia and neurocognitive disorder due to vascular dementia, may have overlapping areas of impairment. Therefore, it is important that evaluators approach each case individually.

For capacity evaluations, functional assessment is vital (Pfeiffer 1991). It is necessary to understand whether evaluees with memory problems can use memory aids, such as mobile devices, calendars, notes, and lists. It is important to elicit whether or not evaluees understand how to use professional help (e.g., bankers, attorneys, etc.) to compensate for their deficits, and whether they know someone they can trust. Evaluees should be able to describe how they know they can trust someone and to be able to recognize ambiguity and uncertainty in their relationships, because the fragile elderly, especially those with psychiatric illness, are more likely to be preyed upon (Lichtenberg et al. 2013). There are a number of tools that supplement, but do not replace, professional judgment in assessing the various capacities. These tools are summarized in Table 77.1.

Health-care consent capacities

As per *Jerry W. Canterbury v. William T. Spence* (1972), health-care decisional capacity is an important component in the triad of informed consent, the other two components being voluntariness and sufficient provision of information on the part of the health-care provider. Most state laws define the capacity to make medical decisions as the ability to communicate a health-care decision based on an understanding of significant benefits, risks, and alternative treatment options.

If individuals lack capacity to make their own health-care decisions, a previously appointed health-care proxy or durable power of attorney can make choices for them. If they had not designated a health-care proxy prior to their becoming incapacitated, many states allow for family members to make medical decisions for them.

In assessing patients' capacity to consent to treatment, evaluators examine their ability to understand relevant information, appreciate the current situation and its consequences, manipulate information rationally, and communicate a choice (Appelbaum and Grisso 1988). Some scholars have advocated for a capacity "sliding scale," wherein stringency of the utilized capacity standard is inversely proportional to the degree of risk of a medical procedure (Freedman 1981; Drane 1985).

Capacity to make an advance directive

An advance health-care directive (also known as a living will, advance decision, or personal directive) is a legal instruction in which a patient designates what actions should be taken for their health if they are no longer able to make decisions for themselves due to an incapacitating condition. An individual's capacity to execute an advance health-care directive is not the same as the capacity to make medical choices. The test of capacity to execute an advance directive is usually the same as that of the capacity to make a contract.

Capacity to consent to physician-assisted suicide

Five U.S. states now allow physician-assisted suicide (PAS), and others have considered permitting it. Oregon, Washington, and Vermont have statutes legalizing PAS, while New Mexico and Montana have set case law standards. If a forensic psychiatric evaluation finds that the patient has a mental disorder causing impaired judgment, treating physicians cannot prescribe lethal medication. Considering the irreversibility of the decision, a forensic psychiatric evaluation should be considered as indicated, even where not legally mandatory, given that primary care physicians do not recognize up to 90% of psychiatric disorders in their patients (Eisenberg 1992).

Several factors make these types of capacity evaluations very difficult. Foremost, as opposed to many other civil and criminal capacities, none of the states that allow PAS have a legal standard for capacity to consent to it.

Additionally, evaluators may be biased with respect to such an emotional topic as life-terminating treatment, especially in the absence of a standard "threshold" for capacity/incapacity (Ganzini et al. 1996; Zaubler and Sullivan 1996). Consequently, treating psychiatrists should not perform capacity evaluations because treating clinicians, as compassionate providers, may be more likely to either unwittingly enable incapacitated, depressed patients' desires to die. Clinicians may also automatically oppose these wishes, given the attachment that can form between treating clinicians and patients.

Although it has not been formally studied in patients requesting PAS, suicidal ideation is generally transient (Falls 2011), and patients with mental illness who want PAS may respond to treatments that are effective in other groups of suicidal persons (Ganzini and Lee 1997). A vital part of any capacity for PAS assessment is to consider whether patients have the capacity to change their mind, love themselves, and maintain a consciousness of time that differentiates transient, potentially treatable suffering from that which is permanent, certain, and intractable (Bursztajn et al. 1986). In summary, the stakes—human life—are enormous, and the potential for unintentional bias is high in these types of evaluations.

Capacity to live independently

The capacity to live independently is usually evaluated as part of determining whether an individual needs a guardian of person. Most states require that for a court to appoint a legal guardian, an individual must have a disabling condition, which usually includes a cognitive deficit; the condition must prevent the individual from performing basic functions necessary to live without assistance; and guardianship must be the least restrictive alternative (Zimny and Grossberg 1998).

Independent living capacity can be affected by a number of psychiatric diagnoses in the elderly, most commonly neurocognitive disorders, depression, or psychosis. When assessing the capacity for independent living, psychiatrists examine whether an individual is endangering himself or herself on account of problems with cognitive, psychiatric, or physical functioning. Functioning is typically conceptualized in terms of basic activities of daily living (BADLs), such as bathing, dressing, and feeding; and instrumental activities of daily living (IADLs), including shopping, taking medications, and managing finances. The ability to do these types of activities requires that a person understand the importance of the task and cognitively and physically be able to execute it. Individuals should also be able to exercise judgment regarding these activities, that is, to perform them consistently and to avoid dangerous behaviors (Zimny and Grossberg 1998; Moye and Braun 2007).

Financial capacities

GENERAL FINANCIAL CAPACITY

Financial capacity is an individual's ability to manage finances in a way that is consistent with personal values. In order to have financial capacity, individuals should be able to carry out financial tasks, such as adding/subtracting currency, managing bank accounts, and paying bills. Furthermore, they should be able to do these tasks in a manner consistent with personal interests and values. Values are particularly important, as individuals tend to differ greatly with regard to why, how, when, and to what degree they spend and invest money. If a court finds that an individual is not able to manage finances, it will appoint a conservator (or guardian of the estate, depending on the jurisdiction) to manage all or some of the finances (Hebert and Marson 2007).

TESTAMENTARY CAPACITY

The ability to execute a valid will, also known as testamentary capacity, is the most commonly contested type of capacity. Moreover, the number of will contests addressing testamentary capacity and undue influence has increased in recent years (Marson and Hebert 2008), as a result of an increase in mixed, nonnuclear families, the transfer of more wealth from the World War II generation (American Bar Association [ABA] and APA 2008), and the increasing prevalence of neurocognitive disorders associated with the aging population.

Most states require that for a finding of testamentary capacity, a testator (man making a will) or testatrix (woman making a will) know the following: what a will is; his or her potential heirs ("objects of bounty"); the nature and extent of his or her assets; and a general plan of distribution of assets to heirs (Roof 2012). (For simplicity, in this chapter we use the term *testator* to refer to both men and women.) If a testator does not understand at least one of these elements, the court may find that he or she lacks testamentary capacity. Consequently, the will, and any modifications to it, will be void. Yet legal standards for testamentary capacity vary greatly by state, so familiarity with the relevant laws of the jurisdiction is imperative.

For a finding of testamentary capacity, a testator must also be able to work with his or her attorney and not hold any delusional beliefs that impact the content of the will (e.g., revising a will to remove as an heiress a daughter who he believes is actually an impostor). Courts have historically applied a low legal threshold for finding testamentary capacity in the interest of honoring the testator's autonomy and freedom to distribute his or her assets. It is therefore important for evaluators to thoroughly understand a testator's lifelong financial values as well as relationships with prospective heirs. A striking departure from long-standing preferences about finances and property could indicate an "unnatural will," a legal term that signals an individual may lack testamentary capacity or be the victim of undue influence (described below).

Undue influence

Undue influence occurs when an influencer subverts a victim's free will, causing the victim to make a decision that

inappropriately benefits the influencer. Additionally, such influence usually contradicts what the victim would have done in the absence of said influence. In forensic psychiatric practice, undue influence is most often encountered in evaluations of testamentary capacity, as it is alleged in over half of contested will cases (Shulman et al. 2005). Undue influence can also impact donative capacity, contractual capacity, and other capacities (Garner 2014).

To find that undue influence occurred, many courts require that a confidential relationship existed between the influencer and the victim; there was a way for fraud to occur; and the victim changed the financial arrangement so that it benefited the influencer. Perhaps most psychiatrically relevant is that the victim must be vulnerable to influence. The greater the neurocognitive and emotional impairment of the victim, the less influence is necessary for the court to find that he or she was unduly influenced (Shulman et al. 2005).

It should be noted that, especially in testamentary capacity cases, psychiatrists are often consulted after the victim has died (Gutheil 2007), and, accordingly, personal forensic evaluation of the victim is not possible. In evaluations in which the testator is deceased, previously administered cognitive instruments such as the Montreal Cognitive Assessment (MOCA) can provide helpful data in the context of all available information.

While reviewing records and performing interviews, geroforensic psychiatrists should consider tactics that perpetrators of undue influence utilize to procure money or goods from their victims. These include keeping victims isolated and unaware of the circumstances; being dishonest (e.g., lying, misrepresenting, or concealing of information for selfish gain); alienating victims from others; using intimidation (e.g., fostering dependency with fear of rejection if money or goods is not willed, or inducing fear by threatening to leave or emotionally/physically harm victims) and generally taking advantage of vulnerabilities; inducing shame and guilt and preying on insecurities; intermittently performing acts of kindness; and promising to care for victims in exchange for financial demands (Hall et al. 2005; ABA and APA 2008). Although there is no complete "profile" of an influencer, many influencers have sociopathic characters and antisocial behaviors, especially a parasitic lifestyle (e.g., living with or financially depending on victims), and/or have psychiatric illness themselves (Hall et al. 2005). When beneficiaries accompany elderly examinees to evaluations, evaluators cannot perform a comprehensive examination for the presence of undue influence.

Additionally, geroforensic psychiatrists should look for several factors that increase the risk of elderly individuals becoming victims of undue influence (Peisah et al. 2009). Demographic factors include advanced age, female gender, and unmarried status. Financial factors include financial independence with no designated money managers and mid- to upper-income bracket. Medical factors include organic brain damage; taking multiple medications; increasing frailty; physical, mental, or emotional illness (especially depression); and cognitive impairment, especially semantic memory deficits. Psychosocial factors include dependent personality traits; recent divorce or spousal death; living with the influencer; fear of change in the living situation (e.g., being placed in a nursing home); dependence on the influencer; and physical and/or social isolation, including estrangement from children (Hall et al. 2005; ABA and APA 2008; Peisah et al. 2009).

ELDER ABUSE

Elders, especially those residing in nursing homes, are particularly vulnerable to physical, sexual, and emotional abuse, as well as neglect and exploitation (Kleinschmidt 1997). Some states legally require clinicians to report suspected abuse or neglect. Federal legislation has also been enacted to combat elder abuse. For instance, the 2010 Elder Justice Act, among other provisions, allocated millions of dollars to establish and support specialized centers for developing forensic expertise on elder abuse, neglect, and exploitation and for providing services to victims (Public Act 111-148 Title VI Subtitle H—Elder Justice Act 2010).

Adult children, spouses, or other family members perpetrate in 90% of cases of elder abuse and neglect (Hildreth 2009). The number of victims is rising, with morbidity and premature mortality growing accordingly (Teaster and Otto 2006). Studies examining the prevalence of elder abuse report that approximately 7%–11% of cognitively intact older adults reported some form of abuse in the previous year (Teaster et al. 2004; Acierno et al. 2010; New York City Department for the Aging Elderly Crime Victims Resource Center 2011).

Unsettling as it may be, this percentage probably underestimates the actual prevalence because many cases of elder abuse go undetected and unreported. However, elder abuse can also be subject to overreporting, due to such misattribution factors as confabulation; paranoia in the face of helplessness; hopelessness and the ravages of time; and family dynamics such as scapegoating dynamics that can be perpetuated by bandwagon or "witch hunt" effects. Older individuals with neurocognitive disorders are especially susceptible because their impairments can render them incapable of reporting incidents.

Because elder abuse and neglect incidents typically happen in more isolated domestic settings, they are not discovered as often as those involving other vulnerable populations. Children, for example, are more often exposed to a wider variety of public areas, such as schools and playgrounds (Hafemeister 2013). Older individuals sometimes cannot make decisions about their living arrangements, and some with neurocognitive disorders do not fully understand or remember abuse or neglect for any meaningful period of time. Moreover, they often cannot reasonably improve their situation on their own. Silence, denial, fear of retaliation, and fear of the unknown can suppress reporting by victims or witnesses of abuse in a variety of care settings.

Risk factors for abuse and neglect include isolation, unfavorable caregiver qualities (particularly a history of antisocial behavior and/or substance use), and victim mental illness, especially neurocognitive disorders. Signs of elder abuse and neglect include atypical injuries; poor hygiene; unsanitary or hazardous living conditions; pressure ulcers; malnutrition and/or dehydration; expressed or apparent fearfulness around caregivers; and depression. Yet no combination of these signs is specific for abuse or neglect, so the presence of one or more of these potential indicators needs to be considered in the context of a broader inquiry (Kleinschmidt 1997).

Clinicians may consult forensic geriatric psychiatrists when elder abuse or neglect is suspected. Factors for forensic geropsychiatrists to consider in more detail include whether fact patterns are more consistent with abuse or neglect or other causes, such as, most commonly, the natural history of a medical or psychiatric disorder. It is also critical to consider whether informants—be they patients, family members, or staff members—are reliable historians. Reasons to question the accuracy of reports include motives such as primary (e.g., a better room in a nursing home) or secondary (e.g., attention seeking due to loneliness) gain. Furthermore, a number of impairments can accompany under- and overreporting, including avoidance of traumatic memories, as sometimes occurs in PTSD; undue influence or dependence on the abuser, which leads to avoidance of reporting of abuse; or patterns of confabulation, as seen in a variety of neurocognitive disorders which can lead to misattribution of abuse. Interviewing methods should avoid suggestion while simultaneously creating a safe environment for evaluees to disclose information that may humiliate and otherwise deeply upset them (Bursztajn 2000).

PSYCHIATRIC MALPRACTICE WITH RESPECT TO ELDERLY PATIENTS

In the general population, the most common type of psychiatric malpractice action arises from suicide of a patient (Simon and Sadoff 1992). Social, economic, and psychological factors increase the vulnerability of older adults to suicidal thoughts and behaviors, and suicide rates are five times higher among elderly males than in other segments of the population (Centers for Disease Control and Prevention [CDC] 2012). A neurocognitive disorder diagnosis further increases risk of completed suicide (Haw et al. 2009; Scocco et al. 2009; Seyfried et al. 2011). The larger number of malpractice suits after elderly patient suicide reflects the high rate of suicide in older adults.

Another common area of geriatric psychiatric malpractice is harm allegedly caused by medications. Polypharmacy in the elderly increases the risk of psychiatric malpractice allegations. As mentioned above, one out of six people age 65 or older is taking 10 or more medications (Guthrie et al. 2015). Despite the U.S. Food and Drug Administration's (FDA) caution in 2005 that atypical antipsychotics increase risk of all-cause mortality by 60%–70% with daily administration over a short period of time (FDA 2005), clinicians continue to prescribe these medications for psychotic and behavioral symptoms. This is particularly true in nursing homes, where residents are more severely cognitively impaired on average than their peers in the general community (Taylor et al. 2012).

Obtaining informed consent from patients, or their legally authorized medical decision makers, is critical when treating elderly individuals, especially with antipsychotics. As with all informed consent evaluations, and even more so with the fragile elderly who may be experiencing great fear or demoralization that may compound information processing impairments, effective, meaningful informed consent is not *pro forma* and does not rely solely on paper forms, which could contain either excessive or insufficient information. Instead, informed consent becomes more of a therapeutic alliance-based process. This process can have therapeutic and risk management benefits for patients, families, and clinicians. A geroforensic psychiatric consultant can aid this process and manage risk associated with treating marginally competent elderly patients (Gutheil et al. 1984; Gopal et al. 2012).

ASSESSMENT AND DETECTION OF MALINGERED NEUROCOGNITIVE DEFICITS

In almost any forensic evaluation, malingering should be ruled out. Dissimulation is an especially relevant consideration in capacity evaluations. Evaluees may "put on their best face" in an effort to persuade psychiatrists that they are not incapacitated, in order to maintain their independence. Cognitive deficits have historically been considered easy to feign, likely due to the presumed ease with which a person can convincingly feign deficits, as opposed to positive symptoms. One of the simplest strategies for detecting malingering is to identify discrepancies between reported symptoms and objective data on cognition found in the mental status examination, written records, and collateral interviews. Yet clinical assessment and collateral data alone often do not sufficiently exclude the possibility of malingering. Several strategies can be useful to assess suspected malingered cognitive problems. These include comparing performance on psychological instruments to that of test-takers with known cognitive impairment, overreporting detection, symptom validity testing (SVT), and the floor effect.

CRIMINAL AND CORRECTIONAL ISSUES IN THE ELDERLY

Criminal behavior in older adults

Older individuals commit far fewer crimes of every type than do their younger counterparts (Barak et al. 1995). Approximately 15% of older individuals apprehended

are arrested for serious felonies (Aday and Krabill 2006). Research shows that elders tend to receive less harsh sentences than their younger counterparts for many different crime types (Steffensmeier and Motivans 2000).

Violent offenses committed by the elderly

International studies have shown that 11%–14% of indictable offenses committed by older offenders were violent ones (Barak et al. 1995; Home Office 2000). Most risk assessment instruments were not developed using groups of older individuals, nor have they been studied in such populations to date. For instance, the MacArthur Violence Risk Assessment study data that were used to design the Classification of Violence Risk (COVR) excluded individuals over 40 years old (Monahan et al. 2000). Additionally, the average age of the 618 offenders studied in the development of the Violence Risk Appraisal Guide (VRAG) was 28 at the time of the offense (Harris et al. 1993).

Geriatric sexual offenders

The majority of sexual offenders and sexual offense recidivists are younger men. Lower overall rates of offending and recidivism among older men are likely due to the fact that they tend to have better self-control (Hanson and Thornton 2003) and poorer sexual functioning (Barbaree et al. 2003) than younger men. Yet nearly 4% of all people arrested for sex crimes in 2006 were 60 or older (Hart 2008). Older sexual offenders are more likely to commit "nonviolent" offenses such as exhibitionism than "violent" offenses such as rape (Alston 1986; Flynn 2004), and are more likely to select children as victims than are younger sex offenders (Hucker 1984).

In terms of sexual recidivism risk factors, having a stranger victim was the strongest risk factor in those over 55, whereas it was not associated with recidivism in those under 25 (Fazel et al. 2002). The age of individuals who have committed rape is inversely correlated to sexual recidivism rates, which is not true of other sexual offense types (Hanson and Thornton 2003).

Psychiatric disorders among the incarcerated elderly

Up to half of older prisoners have a psychiatric illness (Fazel et al. 2001; Fazel and Danesh 2002), whereas only about one in seven prisoners of all ages have a treatable mental illness (Fazel and Danesh 2002). Rates of psychosis and depression each represent about a third of psychiatric illness in older prisoners, which is higher than in prisoners of all ages (Fazel and Danesh 2002).

Despite such high prevalence rates, older individuals are less likely than younger ones to receive treatment. This may be due to the fact that they are not as inclined to acknowledge psychiatric symptoms, even when treatments are available (Vega and Silverman 1988; Yorston and Taylor 2006; Sterns et al. 2008). Similar to the nonincarcerated general population, older incarcerated individuals are more likely to attempt and commit suicide than younger cohorts (Kuhlmann and Ruddell 2005). Additionally, as with younger inmates (James and Glaze 2006), psychiatric illness is far more common in incarcerated women than men (Aday and Krabill 2011).

Substance use disorders among the incarcerated elderly

Like the general incarcerated population, the elderly incarcerated are more likely to use substances than their nonincarcerated cohorts. In an Iowa survey, 71% of prisoners age 55 and older reported a history of substance use consistent with a substance use disorder, compared with more than 90% of younger prisoners. Among elderly offenders who report substance use disorders, alcohol use disorder is most common. Its prevalence of 85% in aged offenders is higher than in younger age groups. Elderly prisoners are also more likely to be arrested for alcohol-related crimes than younger prisoners (Arndt et al. 2002).

SUMMARY KEY POINTS

- As the elderly live longer and medical knowledge increases, geroforensic psychiatry has become a rapidly growing field, one that requires sensitive and comprehensive evaluation.
- Increasing prevalence of neurocognitive disorders with age results in older individuals being more likely to have their capacities evaluated.
- Treating clinicians may consult geroforensic psychiatrists in suspected elder abuse cases.
- Elder patient suicide and adverse drug reactions are common causes for medical malpractice lawsuits against geropsychiatrists.
- Geroforensic evaluators should always consider malingering, particularly malingering of neurocognitive symptoms.
- The prevalence of psychiatric and substance use disorders is higher among older inmates than younger inmates, yet this group is less likely to receive treatment than younger inmates.

Gender issues in forensic psychiatry

RENEE M. SORRENTINO AND SUSAN HATTERS-FRIEDMAN

INTRODUCTION

This chapter explores the impact of gender on forensic psychiatry. The first section addresses gender issues related to evaluees and expert witnesses. The second section focuses on special topics in gender bias. In reviewing these subjects, it is important to keep in mind the role of stereotypes in gender biases. There is no question that gender differences exist in many areas of forensic psychiatry. The relevant question—whether these differences are correct or whether they are inaccurate and translate into a distorted understanding of forensic issues—remains elusive. The answer to this question will help us to understand whether males and females should be treated differently, or rather whether differences are the product of stereotypes that would be best addressed through education.

GENDER ISSUES RELATED TO EVALUEES

Gender differences in legal outcomes

When the role of gender in the determination of legal outcomes is examined, often studies conclude that female defendants receive more lenient sentencing than male defendants. For example, for charges resulting from death, a woman is more likely than a man to be incarcerated for manslaughter rather than murder (Carson and Sabol 2012). Less studied, however, is whether gender bias is present across all types of offenses, or whether the bias is more substantial for certain criminal behaviors. Rates of incarceration of women in the United States are on the rise. Incarcerated women are more likely to be mentally ill. The two most common Axis I diagnoses among incarcerated women are posttraumatic stress disorder (PTSD) and substance use disorders (Friedman et al. 2013; Friedman et al. 2016). Bipolar disorder may also increase criminality in women (Friedman et al. 2005).

Studies that evaluate the role of gender in competency to stand trial adjudications have largely found no association between gender and competency findings (Riley 1998; Cooper and Zapf 2003; Kois et al. 2013). Gender differences in not guilty by reason of insanity (NGRI) acquittees indicate that women found NGRI are older, more often married, less often substance abusers, and less often have criminal histories than the male counterparts (Tonana et al. 1990; Seig et al. 1995). Women were more likely than men to have a diagnosis of borderline personality disorder or a mood disorder (Ferranti 2013; Friedman et al. 2013).

Specific crimes have gender differences in outcomes. For the crime of filicide (child murder by the parent), fathers are far more likely than mothers to be incarcerated (Friedman et al. 2012). Mothers are more likely than fathers to be found NGRI (Friedman et al. 2005).

McKelvie (2002) studied the effect of the sex of the judge and sex of the victim on sentencing in hypothetical vignettes of a male murderer. Female judges gave longer sentences in cases of female victims, whereas male judges gave longer sentences in cases of male victims (McKelvie 2002).

The presence of gender disparity in criminal sentencing raises the question of whether men and women should be treated equally when it comes to punishment. Are there evidence-based reasons for the disparity? For example, do women receive more lenient sentences because they are less likely to engage in future violent criminal acts? Or, is the disparity based on the bias of our society, culture, and media that depict men as violent and women as docile? How do these biases affect our ability to recognize and evaluate female offenders? The answers to these questions are tied with our further understanding of the differences between male and female offenders.

Women prisoners have higher rates of mental illness than female community counterparts, and perhaps higher rates than male offender counterparts as well. Women prisoners have often faced multiple life stressors and have elevated rates of substance use disorders. Lewis noted: "The portrait of the female offender that emerges from existing literature is of a polysubstance-dependent minority single-mother in her child-bearing years with a history of psychiatric treatment, physical or sexual abuse often dating to childhood, and socioeconomic hardship" (Lewis 2006, 782).

Gender issues related to expert witnesses

Surveys of courtroom experts suggest that women more frequently experience gender discrimination (Price et al. 2004). Research on how the gender of the expert is perceived by judges and juries is variable. The gender of the expert may be perceived as positive, negative, or neutral depending on the study. Neal et al. (2012) found the gender of an expert was relevant only when the expert was not high in likability and knowledge. In this setting, males were viewed more favorably than females. Schuller et al. (2005) investigated whether the influence of the gender of an expert witness on jurors varied with the complexity of the expert's testimony in a simulated civil trial. They found that gender impacted on the jurors' receptivity to the testimony. More specifically, Schuller et al. (2005) found that the male expert was more persuasive then the female expert when the testimony presented was complex. In contrast, female experts were at an advantage in the low-complexity cases. A study by Couch and Sigler (2002) found individual mock juror response measures indicated no significant effect of gender on the effectiveness of the expert witness. The conflicting findings in these studies may be related to the specific type of case (Couch and Sigler 2002; Price et al. 2004; Schuller et al. 2005; Neal et al. 2012). For example, an expert's gender may be a major factor in the selection of an expert in cases of sexual harassment, "battered woman syndrome," or sexual offenses. In a survey of 94 forensic psychiatric members of a professional organization, 80% of women believed that gender was a consideration, whereas only 41% of men believed male gender to be relevant in the acquisition of cases (Price et al. 2004). In the same survey, 60% of female experts reported attorneys expressed a preference for the gender of an expert on a particular case. Only one-quarter of male experts had such an experience. Female experts were considered desirable in cases of sexual harassment and in sexual offenses.

SPECIAL TOPICS WITH POTENTIAL GENDER BIAS

The role of gender bias varies depending on the specific topic. In this section the impact of gender bias is explored in the following areas: sexual offenses, sexual harassment, transgenderism, stalking, and domestic violence. Understanding gender disparities in these areas is necessary to the pursuit of objective evaluations.

Sexual offenses

Little is known about female sex offenders due to a scarcity of research. Additionally, the cultural and societal perceptions of females as maternal and altruistic influence the objective investigation of females as perpetrators of sexual offenses. Female sex offenders are often misperceived of as rare and harmless. As an illustration of this cultural bias toward females, an Internet search for female sexual offenders identified sites such as "hottest females sex offenders," "teacher appreciation week: hottest female sex offenders," and "hot for teacher." A sexual act between a boy and an adult woman may even be viewed by some as a rite of passage. In contrast, male sexual offenders tend to be viewed as violent and dangerous with intent to inflict harm. Without more research in this area, the appropriate treatment and management of female offenders remain in question.

In the United States, women perpetrators account for approximately 2% of sexual assaults reported by victims (Greenfield and Snell 1999). The arrest rate (defined as arrests/100,000 persons) for forcible rape in the United States in 2012 was 13.2 for men and 0.1 for women (U.S. Census Bureau 2010).

It is difficult to understand the true prevalence of female sexual offending due to the likelihood of underreporting when the offender is female (West et al. 2011). In fact, self-report studies in which victims are asked to identify the gender of the perpetrator suggest that female sexual offenders are not rare. Petrovich and Templar (1984) found that 59% of 83 prisoners convicted of rape had been molested by a female in childhood. Mendel (1995) studied 121 sexually abused males receiving therapy in both private and community mental health clinics. The majority (60%) of his sample reported childhood sexual activity with females. Demaré et al. (1993) examined self-reported sexually aggressive behavior among men and found that sexually abused men were more likely to report having pressured women into sexual intercourse. Among the sexually abused men who reported sexual aggression against women, 80% had been sexually abused during childhood by a female perpetrator.

If self-report studies indicate female sexual offending is not rare, how do we reconcile the low rate of charged sexual offenses committed by females? Gender bias may be the answer. Authors Mendel (1995), Allen (1990), and Denov (2001) suggest that sexual abuse by females is not recognized as a result of traditional sexual scripts that depict women as incapable of committing sexual offenses. Studies of the general population have provided empiric evidence for the notion that female sexual offending is not recognized (Finkelhor 1984; Broussard et al. 1991). Gender bias is also apparent in the language of the laws that govern sexual offenses. Several American states have laws that define rape as perpetration by a male against a female. In Missouri, females can be found guilty of rape where she aids a male in committing the rape, but cannot commit a rape on her own (Denov 2003). Professionals' responses to sexual abuse by females may also be subject to gender bias. The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), indicates the paraphilic disorders are substantially fewer in females compared with males (American Psychiatric Association [APA] 2013). Finkelhor et al. (1988) found police and prosecutors' responses to female sexual offenders were more ambivalent when compared with male offenders. Without gender-sensitive studies and gender neutrality of governing laws, society is at risk

of ignoring female sexual offending and thereby creating a risk to the community. Forensic psychiatrists must guard against perpetuating similar gender misconceptions in evaluations.

Most studies investigating the differences between male and female sexual offending are limited by small samples. Research suggests substance abuse, psychological diagnoses, and criminal histories are more severe among male sex offenders (Johansson-Love and Fremouw 2009; West et al. 2011). Williams and Bierie (2014), utilizing a large sample, compared male and female sex offenders among 802,250 incidents of sexual assault reported to authorities over a 20-year period. Similarities between genders included the following: the home was the most common offense location; the most common victim-offender relationship was acquaintance; and a rarity of injuries or drug abuse during crimes. The differences between the genders included the following: the females were more likely to have male accomplices (30% versus 2% of males) and were more likely to offend against a victim of the same sex (50% versus 10% of males) (Williams and Bierie 2014). With regard to victim selection, female sexual offenders are described as less discriminating toward the gender of victims than male sexual offenders (Denov 2004), offending against both males and females (West et al. 2011). Women tend to know the victims, and to victimize children (West et al. 2011).

There is little empirical evidence about treatment efficacy or sex offender recidivism in females. In contrast, there are many studies investigating recidivism in male sex offenders and treatment outcomes. Female sex offenders have an estimated 5-year recidivism rate of 1%–3% compared to the 10%–15% recidivism rate of males (Cortoni and Hanson 2005; Poels 2007). However, it remains possible that recidivism is missed because of gender bias in reporting arrests. Sandler and Freeman (2009) found some important distinctions between female and male sex offender recidivists. In a study of 1466 females convicted of a sexual offense in New York State, the authors found an opposite relationship between age and likelihood of sexual recidivism for female and male sex offenders—with the likelihood of sexual recidivism actually increasing with age for females (Sandler and Freeman 2009). They also found a prior history of violent crime was not significantly related to likelihood of sexual recidivism for female sex offenders—unlike male sex offenders (Sandler and Freeman 2009).

Research on sentencing differences as a function of sex offender gender consistently finds women receive more lenient sentences (Koons-Witt 2002; Jeffries et al. 2003). Embry and Lyons (2012) examined the sentencing discrepancies between male and female sex offenders reported in the National Corrections Reporting Program data for the years 1994–2004. The authors found a significant difference in sentence length between men and women. The mean sentence length for men was longer than for women indicating a harsher penalty for the same or similar offenses (Embry and Lyons 2012). They did not find any instances in which women were sentenced to longer or more severe sentences with regard to any sex offense (Embry and Lyons 2012).

Vandiver et al. (2008) studied the effect of the sex offender registry on female sex offenders in two states. They found all nine female sex offenders reported at least one negative effect on her life as a result of being identified on the public registry (Vandiver et al. 2008). Tewksbury (2004) evaluated the attitudes of 227 women who were registered sex offenders. Approximately one-third of the women reported losing a job, being denied a place to live, losing a friend, experiencing in-person harassment, or being treated rudely in public due to registration (Tewksbury 2004). Similarly, negative consequences of registration have been reported in male offenders (Levenson and Cotter 2005). It is unknown whether the outcomes of registries and public notification differ by gender. For further information about sex offender registry legislation, see Chapter 80.

Females comprise a small minority of those designated as sexually dangerous persons. In general, civil commitment of female sexual offenders presents a challenge. The treatment programs developed for sexual offenders are specific to males, and there is a general lack of gender-specific programming for females within the criminal justice system and the community (Bloom et al. 2003; Schafer 2003). The absence of gender-specific programming and treatment is explained by the lack of research specific to female sexual offenders. As a result, the evaluation, management, and risk assessment for females are largely based on the male sex offender literature and therefore are not evidence based. The repercussions include treatment programs and legal decisions that do not rehabilitate female offenders, or worse, have no impact on stopping sexual offending.

Sexual harassment

In 2011, the U.S. Equal Employment Opportunity Commission (EEOC) reported receiving 11,364 claims of sexual harassment, of which 84% were filed by women (EEOC 2011). The number of claims filed by men has risen from 12% in 1997 to 16% in 2010 (EEOC 2011).

Ellison v. Brady was a landmark sexual harassment case in 1990 that set the "Reasonable Woman" standard in sexual harassment law (Profio 1992). *Ellison* marked a change from such cases as *Rabidue v. Osceola Refining Co.*, which utilized a "reasonable person" standard in adjudicating the plaintiff's sexual harassment claim (Profio 1992). In making its decision, the *Ellison* court stated by requiring the use of the reasonable woman standard in sexual harassment cases, the court attempted to bridge the gap between male and female perceptions of what conduct constitutes workplace sexual harassment (Profio 1992). In years following the *Ellison* ruling, the "Reasonable Woman" standard was renamed the "Reasonable Worker" standard and generalized to include any type of harassment or stalking regardless of the gender of the victim or harasser.

Gold (1998) identifies gender bias as one component of bias in the forensic assessment of sexual harassment claims. The first type of gender bias derives from the traditional view of psychological teaching that focuses on the intrapsychic features of a claimant. Gold (1998) suggests that this focus results in the scrutiny of a claimant's contribution to her problem, rather than evaluating the totality of events including external events. Second, Gold (1998) identifies an inherent gender bias in sexual harassment claims due to the societal and cultural perceptions of gender roles. Gold (1998) suggests that these gender biases be addressed by adherence to the forensic ethical guidelines and familiarity with research related to these issues.

Gender differences in the experience of sexual harassment are not well known. Street et al. (2007) compared the experiences of sexual harassment among men and women in the military. Consistent with previous research, women reported a higher frequency of sexual harassment, and both men and women who experienced sexual harassment reported negative mental health impact. However, more severe sexual harassment was associated with stronger negative mental health symptoms for men than for women (Street et al. 2007).

Gender dysphoria

Among the changes in the *DSM-5* is the change in name from "Gender Identity Disorder" to "Gender Dysphoria." This change reflects an attempt to destigmatize the condition by replacing the word "disorder" with "dysphoria." For a person to be diagnosed with Gender Dysphoria, there must be a marked difference between the individual's expressed/experienced gender and the gender others would assign him or her which leads to clinically significant distress or impairment in social, occupational, or other important areas of functioning for at least 6 months (APA 2013).

Before reviewing gender differences in the transgender population, it is important to define terminology. "Gender non-conforming" is used to refer to individuals whose gender expression is different from societal expectations related to gender. "Transgender" is a term referring to individuals whose gender identity, expression, or behavior is different from those typically associated with the assigned sex at birth. An older term, "transsexual," describes individuals whose gender identity is different from the assigned sex at birth who seeks to transition from male to female or female to male (Coleman et al. 2012).

The prevalence of transgenderism is unknown. Studies have relied on reviews of community samples of the following: individuals who are diagnosed with Gender Identity Disorder (GID), parental endorsement of behavioral items pertaining to GID, or the number of adult patients seeking contra-sex hormonal treatment or sex-transformative surgery at hospital- or university-based gender clinics (Zuker and Lawrence 2009). The prevalence figures reported in 10 studies in eight countries range from 1:11,900 to 1:45,000 for male-to-female individuals (MtF) and 1:30,400 to 1:200,000 for female-to-male (FtM) individuals (Zucker and Lawrence 2009).

As the public has become more aware of transgendered individuals and the unique legal challenges facing this population, legal protections have evolved. Today, legal protection in the areas of employment discrimination, marriage, child custody, health care, prison safety, hate crimes legislation, and asylum have been afforded in varying degrees to transgendered individuals (Transgender Law and Policy Institute 2010). However, transgendered individuals have not been afforded equal legal protection in all areas. Both the Rehabilitation Act of 1973 and the Americans with Disabilities Act (ADA) explicitly exclude both "transsexualism" and "gender identity disorders not resulting from physical impairments" from protection (Civic Impulse 2014). States have varied in interpretation of transsexualism as a disability. Some state laws include explicit exemptions for transsexual people while others have found that transsexualism is a protected disability under state laws.

Discrimination and general ignorance surrounding transgendered individuals has led to marginalization affecting access to housing, employment, and competent health care (Wall 2014). Although the overall prevalence of transgendered individuals in the correctional setting is low, approximately 14% of transgendered individuals in San Francisco reported having been incarcerated at least once (Minter and Daley 2003). Findings from the Bureau of Justice Statistics' third National Inmate Survey, from 2011 and 2012 show that inmates who self-identified as gay, lesbian, bisexual, or other reported higher rates of both being sexually victimized by another inmate and being sexually victimized by staff (Beck et al. 2013).

The legal challenges arising when transgendered individuals are incarcerated include the right to treatment and protection of an individual's Eighth Amendment rights. The 1976 landmark legal decision in *Estelle v. Gamble* established the legal precedence that "deliberate indifference to serious medical needs of prisoners constitutes the unnecessary and wanton infliction of pain" is in violation of the Eighth Amendment. The application of *Estelle v. Gamble* to the transgender population relates to whether incarcerated transgendered individuals have a right to the standard treatment available in the community for this population. The right to medical treatment for transgendered individuals has been widely litigated, and court opinions on this subject have changed over time. In *Meriwether v. Faulkner* (1987) the U.S. Court of Appeals for the Seventh District Circuit opined that "a transsexual inmate is constitutionally entitled to some type of medical treatment, however, the inmate does not have a right to any particular type of treatment, such as estrogen therapy" (*Meriwether v. Faulkner* 1987). Many cases that exclude hormonal therapy or sex reassignment surgery cite private and public medical insurances, such as Medicare and Medicaid, which have denied such treatments (*Maggert v. Hanks* 1997).

However, in cases in which a transsexual prisoner's hormonal treatment was discontinued due to incarceration, the courts ruled that such abrupt termination of treatment qualified as "deliberate indifference" (*South v. Gomes* 2000; *Wolfe v. Horn* 2001). These cases together with the 2005 U.S. Bureau of Prisons Program Statement on Patient Care established the guidelines of approving treatment for transsexual prisoners if the treatment predated incarceration. The Federal Bureau of Prisons' policy on hormonal treatment of transsexuals was coined the "freeze-frame" policy, referring to the "freeze" on treatment once an individual is incarcerated (Simpopoulos and Khin Khin 2014). This freeze-frame policy has been modified as a result of the 2010 *Adams v. Federal Bureau of Prisons* settlement. In the settlement, the Federal Bureau of Prisons agreed to implement an official policy memorandum stating that individuals in custody with a possible diagnosis of GID will receive an individualized assessment and evaluation and that treatment plans will be developed based on current accepted standards of care for GID and will not depend on the individual having received GID treatment prior to incarceration (*Adams v. Federal Bureau of Prisons* 2010). In *Kosilek v. Spencer* (2012) a U.S. District Judge in Massachusetts ruled that the Department of Corrections (DOC) had violated Kosilek's, a transgendered inmate, constitutional rights under the Eighth Amendment by denying sex reassignment surgery. The DOC was ordered to provide Kosilek with sex reassignment surgery. The DOC has appealed the case.

Incarcerated transgendered individuals have typically been classified and housed according to the external genitalia. Some facilities have addressed the housing of transgendered individuals by placing them in segregation. Litigation in the housing and classification of transgendered individuals is similarly based on the Eighth Amendment. In *Farmer v. Brennan* (1994) a transgender female inmate filed action against the prison claiming the prison officials were responsible for her being beaten and raped by another inmate because they placed her in a vulnerable environment. The Supreme Court ruled that a prison official's "deliberate indifference" to a substantial risk of serious harm to an inmate violates the cruel and unusual punishment clause. The Supreme Court further defined "deliberate indifference" as "the official must both be aware of facts from which the inference could be drawn that a substantial risk of serious harm exists, and he must also draw that inference" (*Farmer v. Brennan* 1994). As the knowledge and understanding of the transgender population grows, both with the support of advocacy organizations and case law, some jurisdictions have developed policies addressing the management and housing of transgender individuals.

Stalking

Depending on the study, women represent somewhere between 9% and 32% of stalkers (Zona et al. 1993; Strand and McEwan 2012). Yet, women are rarely prosecuted for stalking when compared to men. In fact, if a man reports that he is being stalked by a woman, he may have the experience of being told he is "lucky" and should be "flattered." One study found that women who stalked were physically violent in one-quarter of cases, though injuries usually did not require medical care (Meloy and Boyd 2003). Violence was more likely in cases where there had been previous sexual intimacy. An Australian study of referrals to a community forensic team specializing in stalking found half of the women had a personality disorder, and 30% had a delusional disorder (Purcell et al. 2001). Women were likely to stalk someone they had known, and 40% stalked professional contacts, such as doctors. Female stalkers are more likely than male stalkers to stalk victims of the same gender (West and Friedman 2008).

Purcell et al. (2001) found that the rates of threats and assaults by female compared to male stalkers were not significantly different. However, female stalkers were less likely to proceed from threats to assaults. Female stalkers were less likely to follow the victim and less likely to have a history of substance abuse or arrests. A study of Swedish and Australian female stalkers found that women were more likely than male stalkers to have borderline personality disorder (Strand and McEwan 2012). Women were more likely to stalk by telecommunication/email while men were more likely to follow. For both genders, there was an 80% chance of violence if the stalker: had a prior intimate relationship with the victim, used approach behavior, and was making threats (Strand and McEwan 2012). This implies that being stalked by a woman rather than a man does not predict a lack of violence. Female and male stalkers may have more in common than they have differences. Stalking by women should be taken just as seriously as stalking by men, and women's risk of violence in stalking should not be underestimated (Friedman 2015).

Domestic violence

Intimate partner violence (IPV) includes physical, sexual, and emotional abuse. The U.S. lifetime prevalence of physical assault by a partner is 9%–30%, and of rape is 8% (Friedman et al. 2008). The forensic psychiatrist must be aware that not only is violence perpetrated by male partners on female victims, but also perpetrated by women on men, can be bidirectional in relationships, and occurs in homosexual relationships as well. Mutual violence ("bidirectional reciprocal aggression"), violence out of anger, violence seeking revenge and control, as well as violence that the violent partner considers as self-defense (paranoid or not) may occur (Friedman et al. 2011). In addition to physicians failing to inquire about domestic violence, patients may not report victimization due to shame, or due to acceptance of the abuse. Women with severe mental illness may be particularly vulnerable to IPV victimization, perhaps related to low self-esteem, planning issues, and impaired judgment (Friedman and Loue 2007). Physicians should

consider routinely screening for IPV, which can begin with a discussion about decision-making and anger in relationships. Symptoms of PTSD may also be screened for, because the prevalence of PTSD in victims of IPV has been found to be as high as 63.8% (Golding 1999).

Personality characteristics of batterers vary. Hamberger and Hastings (1988) described male batterers as moody and emotional, cold and calculating, or insecure and jealous. Similarly, female batterers may be compulsive, histrionic, and/or narcissistic (Buttell and Carney 2005). Courts often mandate participation in domestic violence intervention programs. However, the effectiveness has been questioned.

Forensic psychiatry's involvement in IPV cases includes reporting issues, risk assessments, court reports for mitigation of penalty and treatment recommendations, as well as potential evaluations for "battered women's syndrome" defenses. Therefore, the evaluator must have an understanding of patterns and motives in IPV. While states require reporting of child abuse, laws about reporting of IPV are more disparate. Many states, however, require reporting of injuries that occur due to crime—and IPV is a crime (Friedman et al. 2008). Arguments against reporting, however, include confidentiality issues, risk for abuse in retaliation, and deterrence of victims seeking treatment. Furthermore, in completing a risk assessment, it is important to consider that in some cases, legal sanctions and separation can increase risk. Restraining orders (civil protection orders) do not guarantee safety and are often violated.

"Battered women's syndrome" (BWS) is not a *DSM*-defined disorder. BWS has been described as related to the concept of "learned helplessness" related to chronic abuse victimization, symptomatology, and patterns of thought that arise. BWS may be correlated with PTSD symptoms. BWS is used in the legal arena as part of an affirmative defense, of imperfect self-defense. Therefore, this requires that the woman admit to the crime, but offer an explanation as to why it occurred. If a woman in an abusive relationship subjectively believes that her life is in acute danger, then the BWS defense might be used to help explain to the jury why her action of killing her partner was understandable in the context of her life circumstances. The forensic psychiatrist's role in a BWS case may be to help describe the context of the violence, use of excessive force, and impact of violence on symptomatology, as well as to explain to the court about the model of "learned helplessness" (Friedman et al. 2008). Criticisms of BWS include the lack of definition in the scientific literature, the use of BWS only in situations involving murder of a partner, and the expectation that learned helplessness is the only model—and that a woman is merely a passive abuse victim.

SUMMARY KEY POINTS

- Women may be more leniently sentenced than men for various crimes.
- Incarcerated women have higher rates of mental illness than their community counterparts.
- Gender of the expert witness may be a factor in expert choice.
- More research is needed about gender issues in sex offenders, sexual harassment, transgenderism, stalking, and partner violence.
- The forensic psychiatrist should guard against potential gender bias by critically analyzing whether perceived gender differences are based on data or assumption.

Substance abuse and addiction

GREGORY SOKOLOV

INTRODUCTION

Substance abuse and addiction issues may present in a variety of medico-legal contexts. Examples in the civil law include personal injury and wrongful death actions alleging negligent prescribing practices or use of a manufactured product, malpractice allegations of physician impairment due to substance use, state medical board actions, denial of life-insurance benefits, termination of parental rights, child custody, employment, and disability. Examples in criminal law include diversion treatment as an alternative to incarceration and mitigation of mental state for specific intent crimes (i.e., premeditated murder).

ADDICTION: DEFINITIONS

A long-standing definition of addiction is that it is "a primary, chronic, neurobiologic disease, whose development and manifestations are influenced by genetic, psychosocial, and environmental factors" (American Academy of Pain Medicine 2001). In this group's definition, addiction often is characterized by behaviors that include impaired control over drug use, craving, compulsive use, and continued use despite harm.

A newer definition describes addiction as "a primary, chronic disease of brain reward, motivation, memory, and related circuitry. Dysfunction in these circuits leads to characteristic biological, psychological, social, and spiritual manifestations." It also states that addiction is characterized by "inability to consistently abstain, impairment in behavioral control, craving, diminished recognition of significant problems with one's behaviors and interpersonal relationships, and a dysfunctional emotional response" (American Society of Addiction Medicine 2011).

EPIDEMIOLOGY OF SUBSTANCE USE DISORDERS

The National Survey on Drug Use and Health (NSDUH) is an annual survey sponsored by the Substance Abuse and Mental Health Services Administration (SAMHSA). The survey is the primary source of information on the use of illicit drugs, alcohol, and tobacco in the civilian, noninstitutionalized population of the United States aged 12 years old or older. Approximately 67,500 persons are interviewed in NSDUH.

According to statistics from the 2012 NSUDH, an estimated 22.2 million persons aged 12 or older (8.5%) were classified with substance dependence or abuse in the past year based on criteria specified in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*). Of these, 2.8 million were classified with dependence or abuse of both alcohol and illicit drugs, 4.5 million had dependence or abuse of illicit drugs but not alcohol, and 14.9 million had dependence or abuse of alcohol, but not illicit drugs. The specific illicit drugs with the largest numbers of persons with past-year dependence or abuse in 2012 were marijuana (4.3 million), prescription pain relievers (2.1 million), and cocaine (1.1 million). The number of persons with marijuana dependence or abuse did not change between 2002 and 2012. Between 2004 and 2012, the number with prescription pain reliever dependence or abuse increased from 1.4 million to 2.1 million, and between 2006 and 2012, the number with cocaine dependence or abuse declined from 1.7 million to 1.1 million. The number of persons with heroin dependence or abuse in 2012 (467,000) was approximately twice the number in 2002 (214,000) (National Survey on Drug Use and Health 2012).

NEUROBIOLOGY OF ADDICTION

A number of different neuronal circuits and neurotransmitters have been implicated in the complex neurobiological process of addiction. Positron emission tomography (PET) imaging of brain functioning indicates that dopamine is significantly associated with substance use, specifically in that drugs that are abused by humans increase dopamine in the "reward circuit" of the brain (ventral tegmental area, nucleus accumbens, and prefrontal cortex). This neuronal circuit is believed to underlie their rewarding effects

(Goldstein and Volkow 2011). In addition to dopamine, the neurotransmitters glutamate, gamma-aminobutyric acid (GABA), and opioid neuropeptides are important in this circuitry. Prominent brain structures include the amygdala, nucleus accumbens, and prefrontal cortex (Kalivas and Volkow 2005). Powerful new techniques (e.g., optogenetics and designer drug receptors) are starting to give researchers the potential to systematically investigate all genes, epigenetic markers, and neuronal circuits in better understanding the neurobiological processes leading to addiction. These advances combined with imaging technologies (both for preclinical and clinical studies) have spurred an unlimited growth of datasets transforming the research into the neurobiology of substance use disorders and the factors that modulate risk and resilience (Volkow and Baler 2014).

DIAGNOSES: *DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS*, FIFTH EDITION (*DSM-5*)

Among the major changes, the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*, American Psychiatric Association 2013) has eliminated the *DSM-IV* diagnoses of substance abuse and substance dependence; these were collapsed into one diagnosis named "substance use disorder." More specifically, three of the four substance abuse criteria were added to the substance dependence criteria, "legal problems" was eliminated, and "craving" was added, yielding a total of 11 criteria for the new diagnosis.

Among the rationale for these changes was that while *DSM-IV* substance dependence has been demonstrated to have excellent reliability and validity, *DSM-IV* substance abuse has much lower reliability and validity (Hasin et al. 2013). Furthermore, the *DSM-IV* hierarchical relationship between dependence and abuse created incorrect assumptions that Abuse is a milder form of dependence; all cases of dependence also meet criteria for abuse; and/or abuse is the prodrome of dependence (Hasin et al. 2013). Psychometric research indicated improvement of test–retest reliability of Abuse with removal of the hierarchy; latent class analysis of the combined abuse and dependence criteria suggested that the criteria correlated with a single factor or two closely related factors; item response theory model analysis of the combined criteria indicated "undimensionality"; and there was intermixing of the various criteria across the severity spectrum, with the exception of the "legal problems" criterion (Hasin et al. 2013). A diagnostic threshold of two criteria out of the total of eleven criteria was chosen specifically to achieve close approximation between the prevalence of the new single diagnosis of substance use disorder and the combined prevalence of the two diagnoses of *DSM-IV* abuse and dependence, in order to "avoid a marked perturbation in prevalence without justification" (Hasin et al. 2013, 841). In addition, the diagnosis for a particular substance use disorder has a severity specifier: As a general estimate of severity, a mild substance use disorder is suggested by the presence of two to three symptoms, moderate by four to five symptoms, and severe by six or more symptoms.

Critics have opposed the elimination of Substance Dependence, viewing it as a "helpful unifying heuristic for clinicians, scientists and sufferers for more than 30 years, and has strong empirical support" (Drummond 2011, 892). Additionally, it has been argued that from a prevention perspective, there is a need for a diagnostic category that recognizes problematic and hazardous substance use, as was the intent of *DSM-IV* abuse (Babor 2011). Concern has been expressed about the diagnostic threshold for *DSM-5* substance use disorder, specifically that it being "away from mainstream neurobehavioral theory regarding what constitutes a mental 'disorder' and 'addiction'"; and would allow "so much heterogeneity that the clinical and research utility of the diagnostic category would be greatly compromised" (Martin et al. 2011).

In previous editions of the *DSM*, the dependence diagnosis was considered to be the equivalent of addiction. The collapse of the *DSM-IV* abuse and dependence diagnoses into one diagnosis implies that the new *DSM-5* substance use disorder diagnosis is not equivalent to "dependence" or "addiction." In fact, the *DSM-5* states: "Some clinicians will choose to use the word *addiction* to describe more extreme presentations" (p. 485). It appears that the reader is left to infer that the *DSM-5* diagnosis closest to "addiction" is "severe substance use disorder," which would be a "more extreme presentation." Consistent with this, research in patients in treatment for alcohol, cocaine, or heroin addiction found that of the 11 possible *DSM-5* criteria, the modal number present was 10 (Hasin et al. 2012).

In judicial and legislative contexts, the diagnostic and conceptual discontinuity between *DSM-IV* and *DSM-5* approach to substance use disorders is likely to present challenges, given that the previous *DSM* editions, such as *DSM-IV*, have been cited in court opinions over 5500 times and in legislation over 320 times (Slovenko 2011). Unlike the *DSM-IV* diagnosis of substance dependence, which has been demonstrated by previous research to have excellent reliability and validity, the same is not yet true for *DSM-5* substance use disorder. Therefore, regardless of choice, the forensic psychiatric expert may need a working knowledge of the issues relevant to *DSM-IV* and *DSM-5*, including the changes, rationale, research, criticisms, and relationship of the new substance use disorder to "dependence" and "addiction."

In the "non-substance-related disorders" section of *DSM-5*, which is classified as behavioral conditions that do not involve ingestion of substances but have similar symptoms as substance use disorders, gambling disorder is included. Previously in *DSM-IV*, pathological gambling was included in the "impulse control disorders" rather than in "substance related disorders." Gambling disorder criteria include overlap with substance use disorders, including need to gamble with increasing amounts of money to achieve the desired

excitement, repeated unsuccessful efforts to control or stop gambling, symptoms of restlessness and irritability upon cessation of gambling, and loss of employment or relationships due to gambling. In one recent study, subjects who met *DSM-5* diagnostic criteria for gambling disorder, as compared to those who were classified as "sub-threshold gambling disorder" or "recreational gambling," were at the highest risk for the new onset of co-morbid conditions, including mood, anxiety, or substance use disorders (Parhami et al. 2014).

In the "conditions for further study" section of *DSM-5*, caffeine use disorder and internet gaming disorder are listed. Proposed criteria sets are presented for these conditions on which future research is encouraged, and they are not recognized diagnoses.

ASSESSMENT

There is a large societal stigma against people with substance use disorders, and defendants may be quite averse to acknowledging the full extent or accurate histories of substance use–related problems. As such, all available records and collateral sources of information are especially crucial when performing a forensic evaluation involving an issue directly related to substance use disorders.

The American Psychiatric Association (APA) Practice Guidelines for Treatment of Patients with Substance Use Disorders outline the basic components of a substance use disorder evaluation and suggest the following: a systematic inquiry into the mode of onset, quantity, frequency, and duration of substance use; the escalation of use over time; the motivation for use; the specific circumstances of the individual's substance use (e.g., where, with whom, how much, by what route of administration); the desired effect of the substance used; the most recent dose of each substance used; the time elapsed since the most recent use; the degree of associated intoxication; the severity of associated withdrawal syndromes; and the subjective effects of all substances used, including substances other than the individual's "drug of choice" (APA 2006, 20).

In addition, the APA Practice Guidelines suggest that the evaluator address the following areas: a history of any prior treatment for a substance use disorder, including the characteristics of the treatment such as setting; context (e.g., voluntary or involuntary); modalities used; duration and, if applicable, dose of treatment; adherence to treatment; and short-term (3-month), intermediate (1-year), and longer-term outcomes as measured by subsequent substance use, level of social and occupational functioning achieved, and other outcome variables. Previous efforts to control or stop substance use outside of a formal treatment setting should also be discussed. For individuals who had previous treatment or periods of abstinence, additional history may include the duration of abstinence, the factors that promoted or helped sustain abstinence, the impact of abstinence on psychiatric functioning, the circumstances surrounding relapse (e.g., whether the relapse was related to withdrawal symptoms, exacerbation of a psychiatric disorder, or psychosocial stressors), the individual's attitude toward prior treatment, nontreatment experiences, and expectations about future treatments (APA 2006, 20).

TESTING

A forensic psychiatrist who is assessing suspected current or recent substance use in an individual should also be familiar with current laboratory tests to detect substance use, especially if making specific recommendations regarding monitoring. Blood has the shortest window of detection; most drugs are cleared from the blood at measurable levels in 12 hours or less. Urine has a detection window of about 1–3 days, as most drugs are cleared within this time after the most recent use of the drug, while other substances, such as cannabinols, may have longer detection periods up to several weeks. A standard 1.5-inch sample of head hair contains drug residuals from the prior 90 days, minus the week immediately before sample collection. A sweat patch test can detect substance use for a period of 1–21 days. Carbohydrate-deficient transferrin (CDT) is elevated in 80% of people who drink five or more drinks daily for 1 week or longer (DuPont 1999, 523–524).

INTOXICATION SEQUELAE

A defendant's or victim's loss of memory for events involved in an alleged crime presents significant problems for both the prosecution and defense, and for the forensic psychiatrist who is evaluating mental state at the time of an alleged offense. Amnesia for events during alcohol intoxication involves impairment of episodic memory. Episodic memory, by definition, includes the time, place, and other interrelated circumstances in which the event occurred. This contextual information is a prerequisite for formation of episodic memories. Alcohol's effect on encoding may disrupt the processing of context for the formation of an episodic memory. Alcoholic blackouts have been reported to be most closely associated with rapid rises in an individual's alcohol blood level (Lee et al. 2009).

Cannabis use has been associated with acute (toxic) psychosis, and exacerbation and causation of chronic psychotic disorders (including schizophrenia). A recent large-scale study has provided the first conclusive evidence that cannabis use significantly hastens the onset of psychotic illnesses during the critical years of brain development—with possible lifelong consequences. The first ever meta-analysis of more than 20,000 patients shows that smoking cannabis is associated with an earlier onset of psychotic illness by up to 2.7 years (McGrath et al. 2010).

An evaluation of the criminal responsibility of an offender who has consumed cannabis necessitates knowledge of the effect of the product on the offender's mental state at the time of the alleged offense. However, as

the effects induced by cannabis are numerous and vary with individuals, the forensic psychiatrist should base the diagnosis and his or her evaluation on facts that are as objective as possible. Published guidelines have been proposed for the evaluation of criminal responsibility with relation to cannabis psychosis (Niveau 2002).

Methamphetamine, particularly smoked crystal methamphetamine, has become a major drug of abuse in the United States, where it is manufactured domestically and is relatively inexpensive. Users experience euphoria from this psycho-stimulant, which lasts longer than crack cocaine and does not require repeated re-dosing to maintain the high. However, methamphetamine is perhaps the most neurotoxic drug of abuse. Methamphetamine may cause agitation, confusion, irritability, and impulsivity. Methamphetamine also causes prolonged insomnia. Paranoid psychosis is a complication of chronic heavy methamphetamine use. Delusional thinking may lead to reactive violence aimed at those believed to be threatening harm toward the substance-using individual (National Institute on Drug Abuse 2006). Methamphetamine use in a defendant poses challenges to the forensic evaluator of an insanity defense, due to the fact that the drug may produce sustained psychotic symptoms, even after acute use has subsided, leading some to suggest methamphetamine-induced psychosis has the potential to reinforce "sanist" attitudes and practices among evaluators and courts (Thom et al. 2011).

TREATMENT RECOMMENDATIONS

A forensic psychiatrist may be asked to make specific treatment recommendations for substance use disorders, and may also identify the current stage at which an individual is in his or her recovery. The "Stages of Change" model is useful for conceptualizing an individual's motivation to address substance use problems (Prochaska and DiClemente 1983). The model, derived from research on tobacco cessation, divides the recovery process into sequential stages, with stage-specific goals to achieve before progression. The stages of change are precontemplation, contemplation, preparation, action, and maintenance. The recommended treatment interventions may be matched to the individual's current stage in recovery to enhance commitment to change and to increase the probability of successful change in substance use.

An individual with a substance use disorder should be enrolled in a treatment program of intensity commensurate with his or her level of problems. The Patient Placement Criteria algorithm developed by the American Society of Addiction Medicine assigns a patient within five levels of care (with sublevels): early intervention; outpatient treatment, intensive outpatient/partial hospitalization; residential/inpatient treatment; and medically managed intensive inpatient unit. Individuals are assigned to these levels of care based on six dimensions: intoxication/withdrawal potential; medical conditions and complications; emotional, behavioral, or cognitive conditions and complications; readiness to change; relapse, continued use, or continued problem potential; and recovery environment (Mee-Lee et al. 2001). Individuals matched to treatment placements based on this algorithm have been shown to have better outcomes than mismatched patients (Magura et al. 2003).

SUBSTANCE USE AND VIOLENCE

Active substance use substantially increases the risk of violence for any individual, and particularly by persons with psychiatric disorders. Research findings have shown such dually disordered individuals are more violent as a group than individuals with a psychiatric illness alone; and those with a psychiatric disorder but without substance abuse are no more violent than the general population (Monahan et al. 2001). In addition to an elevated general violence risk, substance use associated with psychiatric disorders with impulse control problems places individuals at a greater risk for threatening violence using firearms (Casiano et al. 2008). As such, it is imperative that a forensic psychiatrist performing a risk assessment for future dangerousness completes a thorough assessment of substance use disorder problems, and offers recommendations, if applicable, to mitigate risk factors for relapse and potential future violence.

CORRECTIONAL SETTINGS

Substance use disorders are rampant in correctional settings, and frequently co-occur with other mental health disorders. Among jail inmates, 76% of all inmates who reported a mental health history also met criteria for a substance use disorder (James and Glaze 2006). The term *substance use disorder* refers to either substance abuse or dependence (using *DSM-IV* criteria).

Substance use disorders increase the risk of criminality, incarceration, re-offense, and poor institutional adjustment (White 1997). Substance-addicted offenders also can present challenges to public safety, public health, and public policy. With the shift toward increased utilization of incarceration (especially for drug offenders) and longer sentences, a major push to expand treatment services has occurred in various correctional settings: prisons, jails, and community corrections agencies. Research confirms that treatment is one of the most effective tools for reducing drug use and recidivism. In fact, the majority of evidence-based practices (EBPs) for addressing drug-involved offenders involve various treatment modalities (Taxman and Belenko 2012, 1–8).

SUBSTANCE USE AND CRIMINAL RESPONSIBILITY

In American and English common law, voluntary intoxication does not fully excuse an individual who

has committed a crime and is not a defense under a not guilty by reason of insanity (NGRI) plea in a general intent crime, although it may result in a diminished verdict or sentence (Slovenko 1995). In the case of *Montana v. Egelhoff*, the United States ruled on the issue of voluntary intoxication, in which the appellant was convicted of premeditated murder and argued he should have been allowed to present evidence of voluntary intoxication to negate the premeditation. The court ruled against the appellant, stating that allowing evidence of voluntary intoxication is not a founded principle of American law that would constitute a violation of the defendant's Fourteenth Amendment rights under the Constitution (*Montana v. Egelhoff* 1996).

In some jurisdictions, chronic substance use leading to psychosis may be the basis for an insanity defense under the concept of "settled insanity." In one paper, Feix and Wolber discuss specific areas that forensic evaluators should consider exploring when evaluating a possible insanity defense associated with substance use. These areas of inquiry include, but are not limited to, (a) whether the defendant exhibited psychotic symptoms only during intoxication or the symptoms seemed to persist after the typical time had passed during which the substance is known to be in its active phase; and (b) evidence of psychotic symptoms or episodes of mental illness before or at times other than when the defendant was intoxicated during the index offense (Feix and Wolber 2007, 181).

Under the concept of diminished capacity, a *mens rea* defense, voluntary intoxication may negate the capacity of an individual to form a specific intent required by the definition of the criminal charge in a specific intent crime (Weinstock et al. 1996). If the requisite specific intent were nullified, guilt could be found for a lesser included crime that does not require the specific intent (e.g., manslaughter instead of second-degree murder).

ASSESSMENT OF ADDICTED PROFESSIONALS

Forensic evaluations of an addicted physician may be part of any of the following: fitness-for-duty evaluation for employer or insurance carrier, state medical board evaluation, malpractice case, or disability evaluation.

Physicians are as likely to experience drug and alcohol addiction as anyone in the general population. Although alcohol is the primary problem in nearly half of all cases, physicians are more likely than others to abuse prescribed medications. In a study of 16 state physician health programs that examined 904 physicians who had been placed under monitoring for drug abuse, more than half of the physicians were in five medical specialties, with family medicine representing the highest number at 20% (McLellan et al. 2008); however, anesthesiologists make up 5.2% of physicians nationwide, and therefore, they are remarkably overrepresented in physician health programs, and most likely to be addicted to intravenous opioids (Kintz et al. 2005).

The following characteristics have been identified as predisposing factors associated with substance abuse in physicians: obsessive–compulsive personality style; family history of substance use disorders or mental illness; childhood family problems; personal mental illness history of sensation-seeking behaviors; denial of personal and social problems; perfectionism; and idealism (Talbott et al. 1998).

Signs that should raise concerns for active substance abuse by a physician may include any of the following: frequent tardiness and absences; unexplained disappearances during working hours; inappropriate behaviors in workplace, affective lability or irritability, interpersonal conflict, avoidance of peers or supervisors; keeping odd hours; disorganization and forgetfulness; diminished chart completion and work performance (Baldisseri 2007).

Attorneys in the United States demonstrate a significant prevalence of substance abuse and other psychiatric disorders, and these often lead to impairment in their professional functioning. One study showed that overall, 33% of attorneys had depression, problem drinking, or cocaine abuse, twice the rates of the general population (Benjamin et al. 1990). Started in the 1980s, Lawyer Assistance Programs (LAPs) exist in most states and usually provide both voluntary and involuntary (discipline-related) services. Similar to Physician Diversion Programs, the goal is to provide clinical monitoring and treatment for mental illness and/or substance use disorders.

SUMMARY KEY POINTS

- An understanding of the basic issues of substance use disorders, including intoxication and withdrawal symptoms, is crucial for forensic psychiatrists, as these disorders may be relevant in many forensic evaluations, both criminal and civil.
- In *DSM-5*, addictive disorders no longer exist as "abuse" or "dependence" but are now combined into "use disorders," with varying degrees of severity.
- The American Psychiatric Association (APA) Practice Guidelines for Treatment of Patients with Substance Use Disorders outline the basic components of a substance use disorder evaluation.
- In American and English common law, voluntary intoxication does not fully excuse an individual who has committed a crime and is not a defense under a not guilty by reason of insanity plea.

Sexually violent predator laws

DOUGLAS E. TUCKER AND SAMUEL JAN BRAKEL

INTRODUCTION

Sexually violent predator (SVP) commitment laws are the latest phase in the long history of legislation in the United States seeking to legally process and clinically treat sex offenders in a manner distinct from other criminal offenders. Washington was the first state to enact an SVP commitment law in 1990 (Wash. Rev. Code. Ann. 1992), with more than a dozen states following within the decade. These laws provide for continued (civil) confinement and involuntary treatment for the most serious and high-risk sexual offenders at the end of their criminal incarceration. The laws have been surrounded by controversy from the beginning, as they try to achieve societally necessary and legally proper results in a conceptually underdeveloped and politically polarized area where the overlap between criminal behavior and psychiatric illness has proven to be especially confounding. In addition to focusing discussion about proper management of criminal behavior in mentally ill individuals, these laws have provided a new arena for the central debate in criminal law over the relative value of public safety versus individual liberty.

It has been noted that laws of the SVP type have a typical life course, beginning with their birth in a state of public fear and outrage over one or more highly publicized sex crimes, subsequent ad hoc legislative committee recommendations and laws created under intense political pressure, and ultimate revision or repeal when the public furor diminishes and the financial and legal repercussions become evident (Sutherland 1950). Part of the reason for this repeated pattern may be the lack of integration between mental health and criminal justice systems in our society. Every time a serious problem is identified in the overlapping area between these two fields, society is surprised anew, and our conceptual confusion in the context of strong emotion leads to yet another policy lurch. Research has indicated that punishment is not as effective as rehabilitation at reducing criminal recidivism for many offenders (Cullen et al. 2000; Birgden 2004), but this has not translated into effective delivery of sex offender–specific treatment, either inside or outside of correctional settings (D'Orazio et al. 2009).

The SVP laws have been subject to repeated legal challenges since their first enactment a decade and a half ago, and while three U.S. Supreme Court forays into this arena (*Kansas v. Hendricks* 1997; *Kansas v. Crane* 2002; *U.S. v. Comstock* 2010) have definitively disposed of some of the major issues, others continue to be subject to litigation, especially at the state level. These include (1) the matter of what treatment is actually being provided under the programs; (2) the issue of confidentiality/privilege in sex offender treatment; (3) the significance and measurement of the subjects' (lack of) control or volitional capacity; (4) the accuracy of estimations regarding sexual recidivism risk at the time of initial commitment as well as at conditional release; (5) the "conditions" of conditional release, including monitoring and treatment procedures; and (6) revocation and recommitment standards and procedures.

Although paraphilic disorders have long been officially recognized as mental disorders, having been listed as such since the earliest classifications of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM,* published by the American Psychiatric Association), they are typically ego-syntonic in that affected individuals often do not see themselves as ill or in need of treatment. These disorders are generally agreed to be biopsychosocial in nature. They affect emotional development, relationships, and behavior, but those so diagnosed typically do not manifest the deficits in reality testing and daily functioning that psychiatrists and others associate with "real" mental illness. The criminal behavior often associated with paraphilic disorders has historically led to a greater measure of involvement by the criminal justice system than the mental health system, and while psychologists and other mental health professionals have developed programs of research and treatment for this population, the field of psychiatry appears thus far to have avoided engagement to any significant extent.

Psychiatrists (and others) have difficulty agreeing on whether or not sex offenders are mentally ill, despite official *DSM* recognition of various paraphilias, and many are uncomfortable with coerced inpatient treatment even if there is agreement on pathology. Involuntary treatment has been accepted by most psychiatrists as appropriate and necessary for individuals suffering from a variety of mental disorders which involve reduced insight and ability to control behavior, such as dementias, psychoses, and addictive disorders, but there has been reluctance to extend this to those with dangerous paraphilic disorders. Many psychiatrists have joined in critiquing the SVP commitment laws as medicalizing a "social problem," and for misusing psychiatry as an agent of social control instead of applying it toward legitimate therapeutic ends, with the implication that the pathology involved in dangerous paraphilias is more "social" than "psychiatric." However, the "social" use of psychiatry is endemic to, if not the essence of, the law/psychiatry interface, and psychiatrists have long been responsible for the care and treatment, as well as custodial management, of sexual as well as other criminal offenders, particularly when it appears that a mental disorder has contributed to the offending behavior. In fact, the differentiation between "criminal" and "mentally ill" behavior is of relatively recent vintage, operationally. For most of recorded history, society's rejects—the poor, the criminal, the mentally ill—were housed in the same facilities. As for paraphilic sex offenders in particular, there has been much debate about whether they are "mad" or "bad," and where they "belong," but by reasonable, defensible standards they are both, and will require integrated legal and mental health interventions in order to effectively address the problems they raise.

What follows is a brief review of the history of laws in the United States governing societal management of sexual offenders, a discussion of the SVP laws in particular, the current treatment being provided for committed SVPs, and some thoughts regarding the implications and future evolution of the legal and clinical management of these complex patient-offenders.

HISTORY OF SEX OFFENDER ADJUDICATION AND TREATMENT

It is important to appreciate that the SVP laws seeking to civilly commit mentally ill sex offenders do not operate in either historical or legal isolation. In response to the same social pressures that led to SVP legislation, other recent legal developments have included sex offender registration and notification statutes as well as laws and ordinances aiming to restrict where these offenders may reside or be employed.

Registration and notification

One does not have to be a student of sex offender legislation to have heard of Megan's Law, named after a young victim of a sexually motivated killing. Megan's Law is often associated with the SVP commitment movement, but it is primarily a registration/notification mandate for sex offenders, initially enacted by the New Jersey legislature in 1994. Subsequent federal legislation, passed by Congress in a 2-year period between 1994 and 1996 (a 1996 part of which is also known as Megan's Law; the others are the Jacob Wetterling Act and the Pam Lychner Act, named after other victims), provides incentives to the states to pass similar legislation in order to create a national database of such offenders, to be implemented in such a manner "as necessary to protect the public." A federal commitment law, the Adam Walsh Act, was enacted in 2006.

The underlying purpose of registration is dissemination and notification—to provide information regarding the identity and whereabouts of sex offenders to relevant groups of citizens and officials. State statutes reflect different ways of providing notification and determining whom to notify—from broad notification of the public at large via postings on the Internet (32 states), to narrow notification of police or other law enforcement agencies only. An intermediate approach involves notification of other "need to know" groups beyond law enforcement, in particular those who work with children or adolescents such as school officials, operators of parks and recreation areas, and staff of various other community organizations. There is substantial variation among the states regarding who is subject to the registration mandate. It can range from all persons convicted of certain statutorily enumerated sex crimes ("offense driven"), to a more discretionary "offender-driven" approach whereby an assessment of the offender's dangerousness (offense severity and likelihood of recidivism) is derived from specific data about the offender and victims. These "dangerousness" assessments may be subject to adversarial argument in a formal hearing. Under the discretionary approach, the length of time that an offender must remain on the registry as well as the availability of the information to outside sources is typically tiered according to a ranking of lower versus higher risk levels.

All 50 states today have sex offender registration and notification laws, which have been supported by several waves of Congressional legislation enacted during the 1990s. The fact that less than half the states have SVP commitment laws shows the extent to which the legal responses of registration and involuntary treatment are separated. Like commitment, registration has a history that well predates the 1990s, and during the twentieth century both have been applied to "habitual criminals" other than just sex offenders. The first registration statute specifically targeting sex offenders was passed by California in 1947. Registration mandates have often commingled sex offenders with other offenders, and it is interesting to note that both sexual and nonsexual offenders have occasionally complained about the relative stigma burdens associated with such lack of differentiation.

Residence and employment restrictions

In addition to sex offender registration requirements, many jurisdictions seek to enhance public safety by restricting residence and employment options. Recent research indicates that 20 states have state-wide statutory restrictions of this kind, while other states have local municipal or county ordinances in place (Hamilton 2011). These restrictions are categorically aimed at individuals convicted of sexual crimes, and are independent of any probation, early release, or parole conditions that might be imposed in specific cases.

Just as some of the objectives of residence and employment restrictions are the same as those of registration and notification statutes, so are many of the corresponding criticisms. These include insufficient differentiation among offenders subject to the restrictions, questionable legislative motivation (protective versus punitive), inadequately identified societal need, and unproved success in furthering the public safety goals. Critics point to the harm done to ex-offenders who wish to resume productive life, given their near-banishment from viable living or working opportunities, which in itself may contribute to criminal and sexual recidivism. For example, research has indicated that residency restrictions have increased homelessness among paroled sex offenders by 800%, which, apart from any humane concerns, is unlikely to promote the public safety objective (D'Orazio et al. 2009). Thus far, however, these alleged punitive motives and consequences have not been deemed sufficient to invalidate the laws for lack of procedural or substantive due process. The courts that have ruled on such constitutional challenges have, analogous to decisions on commitment, been content to honor the declared civil/regulatory purpose of the restrictions.

Commitment laws

Until the late 1930s, sexual offenders in the United States were dealt with by incarceration and punishment like all other offenders. A new era of interest in medical explanations for criminal behavior and an orientation toward treatment goals over punishment began to develop in the early twentieth century. Indeterminate sentencing was introduced, in which release decisions were determined by the offenders' demonstrated rehabilitation rather than by preset sentence limits. Eventually, "sexual psychopath statutes" began to appear in progressive jurisdictions, which provided for civil commitment and treatment of repeat sex offenders who were deemed to be suffering from a mental disorder associated with volitional impairment (i.e., inability to control one's impulses). Michigan and Illinois enacted the first such statutes in 1937–1938, with California and Minnesota following shortly thereafter. The Minnesota statute generated the first constitutional test of this type of legislation before the U.S. Supreme Court, in *Minnesota ex. rel. Pearson v. Probate Court* (1940). The challenge to the statute was on substantive due process grounds, notably the vagueness of the description of those susceptible to the statute's application. The Supreme Court, however, approved the legislation, noting that the key statutory term "psychopathic personality" was adequately defined as involving a "habitual course of misconduct in sexual matters," and an "utter lack of power to control sexual impulses." Between 1940 and 1976, sexual psychopath legislation modeled on the Minnesota statute was passed in 30 other states and the District of Columbia, and it was used to a substantial degree. The rehabilitative ideal behind these laws was widely shared, and the procedural shortcuts permitted by most of these statutes were considered acceptable given the benign intentions and predicted good outcomes (Brakel and Cavanaugh 2000).
